2.4.5.1 Symptoms

There is usually a delay of 1–6 weeks from the start of infection to the onset of arthritis. In about 10–25% of cases, the triggering infection can be asymptomatic. This is especially observed with *Chlamydia trachomatis*. Individuals who are HLA-B27+ have a higher risk of contracting ReA following a triggering infection, but the incidence of B27 positivity amongst individuals who develop ReA after particular infections (e.g. outbreaks of gastrointestinal infection due to contaminated foodstuffs), varies widely. The patients are usually young adults, with a mean age of 30–40 years; in children the disease is uncommon and usually associated with gastroenteritis. Male and female patients have a similar risk for the development of reactive arthritis induced by gastrointestinal infection, while reactive arthritis triggered by *Chlamydia trachomatis* is more frequently diagnosed in male patients.

Patients typically have asymmetrical oligoarthritis, often in large joints of the lower extremities (figure 7). However, about 50% of patients have arthritis also in upper limbs. The disease can also manifest as a mild polyarticular form of arthritis in small joints. Besides arthritis, patients may have dactylitis (figure 8). Patients often have extra-articular inflammatory symptoms and signs (table 4). Enthesitis or bursitis can occur as well as

other extra-articular features, common to other spondyloarthritides. They include eye symptoms (conjunctivitis, and less commonly acute anterior uveitis), various skin symptoms (figure 9), and occasionally onycholysis in prolonged or chronic cases, resembling that seen in psoriasis (figure 10). Carditis is rare, but heart conduction disturbances can be seen occasionally. Urethritis can be a manifestation of infection, especially due to *Chlamydia trachomatis*, but it can also be sterile and occur in reactive arthritides triggered by enteric pathogens. *Salmonella* can also be isolated from urine, although this is very uncommon. About 30% of patients have acute inflammatory low back pain, typically worse during the night, radiating to the buttocks (Leirisalo-Repo, 2005a).

Figure 10 Nail changes (onycholysis) in a patient with chronic reactive arthritis.**Table 4 Clinical features of acute reactive arthritis in a hospital series**

Clinical features	Range*
Number of joints, range	1–24
Low back pain, range (%)	2–67
X-ray sacroiliitis, range (%)	11–20
Urethritis, mean, range (%)	4–93
Conjunctivitis, range (%)	6–78
Iritis, range (%)	6–17
Skin lesions, range (%)	4–14
- Erythema nodosum	
- Pustules	
- Keratoderma	
- Circinate balanitis	
Heart conduction disturbances	<1%
Duration of arthritis, range (months)	1–30
Chronic course (>12 months), range (%)	0–30
HLA-B27+, range (%)	0–94

*Range from several studies reported in the literature.

2.4.5.2 Laboratory diagnosis

The diagnosis of reactive arthritis relies, besides the typical clinical picture, on demonstration of the triggering infection, such as isolation of the microbe or demonstration of antibodies against the microbes. During the acute phase of enteric infections, isolation is usually possible from the stools. However, by the time arthritic complications appear, the patient may have already recovered from the gastroenteritis and the microbe may no longer be detectable, though stool cultures can be positive for up to a month after acute infection. The

laboratory diagnosis is sometimes dependent on serodiagnosis, but unfortunately, there are no international standards for such tests, and the techniques used vary greatly (Hannu et al, 2006*).

Urethritis can be a sign of local infection or an inflammatory, 'reactive' symptom. Genital infections are frequently asymptomatic. Therefore, a high degree of suspicion for chlamydia is relevant for the diagnosis of reactive arthritis and should prompt Chlamydia trachomatis detection in the urogenital tract. Search for chlamydia in the first portion of the morning urine by PCR is currently the preferred test. It is more convenient than a urogenital swab and the results are comparable.

The use of serology for the diagnosis of infections with Chlamydia trachomatis is hampered by a relatively high prevalence of positive antibodies among normal subjects and by a possible cross-reactivity with antibodies directed against Chlamydia pneumoniae. Determination of IgG antibodies is not sufficient, but this should be combined with tests for IgM and IgA antibodies. Positive serology alone without a history of a urogenital tract infection does not suffice to make a definite diagnosis of chlamydia-induced reactive arthritis.

In about 60% of patients with a typical clinical picture of reactive arthritis, evidence of previous infection can be detected either by serology or by cultures from urogenital or stool samples.

Based on hospital series, the occurrence of HLA-B27 has been reported to be as high as 90% but is considerably lower or not raised at all in patients with mild arthritis. Therefore, the use of HLA-B27 as a diagnostic tool is not recommended. If the clinical picture does not strongly favour reactive arthritis, the post-test probability of the diagnosis, conferred by HLA-B27 detection is low.

ESR and CRP are usually raised. Synovial fluid leucocyte count is between 2 and $60 \times 10^9/L$. Other rheumatic conditions, such as Lyme arthritis, gout, early RA starting exceptionally as arthritis of a large joint, viral arthritides and even osteoarthritis, should be excluded on the basis of the clinical picture and/or by relevant laboratory tests.

2.4.6 Treatment

2.4.6.1 Treatment of the triggering infection

All patients with acute Chlamydia trachomatis infection should have routine treatment (eg, azithromycin 2 g as single dose treatment, with partners also treated concurrently). Uncomplicated enteritis preceding reactive arthritis is not an indication for treatment with antimicrobial agents. However, if a patient has had reactive arthritis previously, the option for treatment of uncomplicated enteritis may be clinically justified. Prolonged treatment with antibiotics does not shorten the duration of continuing reactive arthritis triggered by enteric infection. In a prospective, double blind clinical trial comparing duration of doxycycline for Chlamydia trachomatis-induced ReA, prolonged treatment with a 4-month regime was not superior to a short-term 10 days

therapy. (Putschky N, et al 2006). In patients with acute reactive arthritis triggered by *Chlamydia trachomatis*, a 3-month course of tetracyclines may be of benefit. Interestingly, prolonged (6 months) administration of a combination of oral antibiotics (azithromycin + rifampicin or doxycycline + rifampicin for 6 months) in the treatment of chronic arthritis in patients with evidence of persisting chlamydia infection has recently been shown to be effective (Carter et al, 2010*).

2.4.6.2 Treatment of arthritis

The use of NSAIDs, often in full dose, is usually of major benefit. Local glucocorticoid injections can be given and are usually also of benefit in patients with monoarticular or oligoarticular disease, as is usually the case. Enthesopathy also responds to local glucocorticoid injections. Systemic use of glucocorticoids is indicated if the patient is bedridden due to severe polyarthritis, there is high systemic inflammation, the patient is febrile, or, in the rare case of the patient having carditis/atrioventricular conduction disturbances. The patients often need a prednisone/prednisolone dose of 20–40 mg/daily at the start. For spinal pain, NSAIDs with long half-life are preferred by the patient. As the arthritis usually affects joints of the lower extremities, physiotherapy is important to reduce pain, prevent muscular atrophy and prevent loss of range of motion. This is especially important in the case of knee synovitis. Early mobilisation, muscle isometric contractions and partial weight bearing can be started immediately, followed later by active exercise.

Effect of antibiotics on the development of acute arthritis. Although no controlled studies exist, early treatment of the infection with antibiotics, before the arthritis has had time to develop, might prevent the arthritis. However, once arthritis is established, the introduction of antibiotics, except possibly in the case of chlamydia-induced arthritis, does not modify the course of the disease.

When are disease modifying antirheumatic drugs indicated? Methotrexate is useful in peripheral arthritis, especially when the symptoms tend to become subacute or chronic. Sulfasalazine in a dose of 2000mg per day has been shown to be significantly effective as compared to placebo in patients with ReA unresponsive to NSAID therapy (Clegg et al 1996). Sulfasalazine is also effective in chronic reactive arthritis. Biological agents are a new class of drugs shown to be effective in chronic HLA-B27-associated diseases such as in ankylosing spondylitis, chronic spondyloarthritis and psoriatic arthritis. They have been used in single cases of reactive arthritis with severe acute or chronic disease resistant to conventional treatments, with major responses and without any evidence of relapse of the background infection.

2.4.7 Outcome

About 50% of patients recover from reactive arthritis within the first 6 months with the above-mentioned treatments. The outcome is usually good. A prolonged (>1 year) extension of the acute arthritis occurs in 15–20% of patients. After the acute episode, mild joint pain or enthesopathy is common. Also, one-third of patients

have occasional attacks of low back pain. During the following 10–20 years, depending on the triggering infection and on the follow-up time, chronic arthritis is seen in 2–18%, sacroiliitis in 14–49%, and ankylosing spondylitis in 12–26% (Hannu et al, 2006*). Patients with reactive arthritis triggered by urogenital infection seem to be more vulnerable to recurrent urethritides and, consequently recurrent episodes of arthritides. The development of ankylosing spondylitis is more common in such patients than in those with previous reactive arthritis triggered by enteric infections.

2.5 Acute rheumatic fever and post-streptococcal arthritis

Streptococcal sore throat (caused by group A β -haemolytic streptococci) can be complicated by the development of acute rheumatic fever, one of the five major manifestations of which is migratory polyarthritis. The diagnostic criteria of rheumatic fever (the Jones criteria) were last updated in 1992 (Guidelines for the diagnosis of rheumatic fever, 1992) (table 5). According to these criteria, a patient with streptococcal infection followed by arthritis as the only major manifestation, should have at least two other minor manifestations for the diagnosis. Acute rheumatic fever is nowadays a rare disease in developed countries, but is still a ~~major~~ concern in the developing countries.

Table 5 Revised Jones criteria for acute rheumatic fever (Reproduced with permission from Guidelines for the diagnosis of rheumatic fever, JAMA 1992;268:2069–73)

Major manifestations	Minor manifestations	Laboratory findings
Carditis Polyarthritis	Fever Arthralgia	Raised acute-phase reactants: (a) C-reactive protein (b) Erythrocyte sedimentation rate
Chorea	Previous rheumatic fever or rheumatic heart disease	Prolonged P–R interval in ECG
Erythema marginatum Subcutaneous nodules		Supporting evidence of preceding streptococcal infection: (a) Increased ASLO or other streptococcal antibodies (b) Positive throat culture for group A-haemolytic streptococci (c) Recent scarlet fever

Acute rheumatic fever can be suspected in the presence of two major manifestations, or one major and two minor manifestations, if the patient has evidence of preceding streptococcal infection, and other causes of acute arthritis have been ruled out.

Post-streptococcal reactive arthritis In some patients acute monoarthritis or oligoarthritis is preceded by group A streptococcal pharyngitis as the only manifestation without other features of rheumatic fever. This usually develops within 14 days after streptococcal pharyngitis; fever and scarlatiniform rash are often present during the acute phase of pharyngitis, but are absent by the time the arthritis appears. There is a bimodal age

distribution, with a peak at 8-14 years and another at 21-37 years. Contrary to the arthritis of acute rheumatic fever, which is migratory and responds rapidly to acetyl salicylic acid, the arthritis in the post-streptococcal reactive form is prolonged. The patients lack other manifestations of acute rheumatic fever. Some studies have shown that during a later follow-up, some of the patients with post-streptococcal arthritis have had signs of chronic rheumatic heart disease, making the diagnosis of the acute phase questionable. However, a study from the Netherlands showed no increased risk for valvular heart disease during a median follow-up of 8.9 years (van Bommel et al, 2009). Evidently, post-streptococcal reactive arthritis is not a single entity but a spectrum of heterogeneous group of diseases with varying manifestations ranging from acute rheumatic fever like-illness to a form which is simply a post-infectious arthritis A, without satisfying other criteria for acute rheumatic fever. Post streptococcal arthritis is not associated with HLA-B27, does not have the typical extra-articular features of ReA, and is not therefore a true ReA in the spondyloarthritis spectrum.

The treatment of post-streptococcal reactive arthritis consists of eradication of the streptococcus from the throat (with, for example, penicillin as used in the treatment of acute streptococcal tonsillitis) for 10 days. A prolonged use of antibiotics is not of major help and is not recommended, unlike in rheumatic fever, although no controlled studies are available to prove this recommendation. The arthritis can be managed with NSAIDs, and in the case of observed synovitis, intra-articular glucocorticoid injections can be used. If the patient has a severe polyarticular disease, use of prednisone/prednisolone orally, starting with 20–40 mg/day and tapering the dose according to the clinical response is usually sufficient.

2.6 Lyme arthritis

2.6.1 Epidemiology of Lyme disease

Lyme disease (Lyme borreliosis) is a tick-borne infectious disease causing complex clinical symptoms. The infection is caused by *Borrelia burgdorferi* (most prevalent in the USA), *B. garinii* and *B. afzelii*. The risk of infection is variable in geographically different areas, depending on the density of infected ticks, their feeding habits and animal hosts. In Europe, Lyme borreliosis is most common in forests. It has spread into the whole of Europe, except for the warmest and dry areas in the south and the coldest areas in the north. The annual incidence of Lyme disease in the USA is 8/100 000 and in central Europe and in Scandinavia varies from 0.3 to 155/100 000 (Schnarr et al, 2006*).

2.6.2 Clinical features of Lyme disease

The clinical features of Lyme disease are usually divided according to the duration of the disease (acute vs chronic). This difference is often arbitrary. History and clinical symptoms—for example, skin changes, might help in the diagnostic investigation of a patient with musculoskeletal symptoms (table 6). The distribution of clinical features is slightly different between patients from North America and from Europe. Neuroborreliosis is more

common in European patients, while severe and chronic arthritis is more frequently described in North American patients. This is probably due to differences in the bacterial species (see table 6).

Erythema migrans (figure 11) is the hallmark of the primary infection, and is the most common finding, in 70% of patients. Erythema migrans is the only manifestation of Lyme borreliosis that can be reliably diagnosed by clinical examination. About half of patients develop also signs and symptoms of systemic infection (malaise, fatigue, headache, arthralgia, myalgia, low-grade fever and lymphadenopathy). The infection is also readily disseminated, at least in the North American patients.

Acute neuroborreliosis develops in about 15% of patients within weeks to months after the primary infection. Acute carditis is uncommon (occurring in 5% of patients) but it might be the presenting symptom. Borrelia infection can also cause eye inflammation (conjunctivitis and uveitis, most commonly posterior uveitis).

If untreated, borrelia infection may persist for months to years. It can manifest in the skin as chronic atrophic changes (acrodermatitis chronica atrophicans, figure 12), occurring in European patients and caused by *B. afzelii*. The patient may also have neuropathic pain and arthritis in the affected areas. Chronic neuroborreliosis is rare. It can manifest as chronic encephalitis, encephalomyelitis, peripheral neuropathy or cerebral vasculitis. Cognitive disturbances, radicular pain and distal paraesthesia may occur.

Figure 11 Erythema migrans after a tick bite. Copyright Dr Raimo Suhonen (© R Suhonen, <http://www.ihotauti.net>).

Table 6 Clinical features of borreliosis with respect to geographical areas. (Adapted from Schnarr et al, Best Pract Res Clin Rheumatol 2006;20:1099–118*)

Organ system	Clinical symptom	Europe and Asia (<i>B. afzelii</i> , <i>B. garinii</i> , <i>B. burgdorferi</i> ss)	North America (<i>B. burgdorferi</i> ss)
Skin:			
Acute phase	Erythema migrans	Spreading slowly, less inflammation, haematogenous dissemination less common	Local distinct inflammation, systemic symptoms common, possibly frequent haematogenous dissemination
	Lymphocytoma	Rare, predominantly in children	Not reported
Chronic phase	Acrodermatitis chronica atrophicans	Caused primarily by <i>B. afzelii</i>	Rare
Nervous system:			
Acute phase	Meningopolyradiculoneuritis Cranial nerve palsy	Severe radicular pain, meningitis, caused primarily by <i>B. garinii</i>	Meningitis, less prominent radiculoneuritis
Chronic phase	Encephalitis Encephalomyelitis Cerebral vasculitis Peripheral neuropathy	Subtle sensory neuropathy within areas of acrodermatitis Severe encephalomyelitis, spasticity, cognitive abnormalities	Subtle sensory neuropathy without acrodermatitis Encephalopathy, cognitive disturbance
Heart:			
Acute phase	Carditis	Atrioventricular block and subtle myocarditis	Atrioventricular block and subtle myocarditis
Chronic phase	Dilated cardiomyopathy	Described	Not reported
Musculoskeletal:			
Acute phase	Arthritis	Oligoarthritis (less frequent) Less intense joint inflammation	Oligoarthritis (more frequent) More intense joint inflammation
Chronic phase	Arthritis	Persisting arthritis less frequent	Treatment-resistant arthritis in about 10% of patients
	Myositis		
	Bursitis		

Figure 12 Atrophic skin changes in the right hand (Acrodermatitis atrophicans) in a patient with previous borrelia infection. Copyright Dr Raimo Suhonen (© R Suhonen, <http://www.ihotauti.net>).

2.6.2.1 Lyme arthritis

In the USA, where *B. burgdorferi sensu stricto* (ss) is the main infecting agent, arthritis is the most common manifestation of borreliosis. Arthritis can occur early or late after the infection. It is usually monoarticular or oligoarticular, affects large joints (knee, ankle, elbow) and runs a fluctuating course with remissions and relapses. Dactylitis and bursitis have been occasionally described, but sacroiliitis is not a feature. Signs of systemic inflammation are usually mild, and rheumatoid factor is usually absent. Synovial fluid shows active inflammation with WBC counts up to $100 \times 10^9/L$. Polymorphonuclear cells are predominant.

The prognosis of Lyme arthritis is usually good; even when untreated, about 10% of patients recover each year. Erosions are rare. After appropriate antibiotic therapy, 90% of patients recover. A small proportion of patients do not respond to antibiotic therapy. In the USA, about 10% of patients belong to this group. Among European patients, there are fewer such cases.

2.6.2.2 Diagnosis of Lyme disease

Patient history and clinical signs and symptoms, especially the occurrence of erythema migrans are important in the clinical diagnosis. Serology does help in the decision-making in more complicated disease. Borrelia antibodies of IgM class start to rise 2–4 weeks after infection, peak within 6–8 weeks and then production is

switched to IgG class. IgM and IgG class antibodies can persist in some patients for many years, even after treatment. A highly sensitive ELISA test should be used in screening, and if the result is positive or borderline, the result should be confirmed by a specific immunoblot test. Especially in European patients, the test should cover all the relevant species (*B. burgdorferi* ss, *B. afzelii*, and *B. garinii*). After clinically successful treatment, there is no need to control the antibody levels.

Culture of borrelia in skin biopsy specimens and in plasma can be performed; culture of the synovial fluid is rarely successful. Borrelia DNA has been detected by PCR in skin biopsy specimens, cerebrospinal fluid, synovial fluid, blood and urine. It is not a routine method, but can be used as an aid in the differential diagnosis of synovitis. The detection of borrelia by PCR is highly specific, but sensitivity in the synovial fluid at best ~85%.

2.6.2.3 Treatment of Lyme arthritis

Lyme borreliosis is treated with antibiotics, tailored to the clinical picture of the disease. Positive antibodies in an asymptomatic subject are not an indication for antibiotics. Erythema migrans can be treated with amoxicillin 500–1000 mg three times/day or with doxycycline 200 mg/day for 14–21 days. For a child or a pregnant patient, amoxicillin (500–1000 mg three times/day), azithromycin (first day 1000 mg, then 500 mg/day for 5–10 days), or cefuroxime axetil (500 mg twice a day for 14–21 days) (Schnarr et al, 2006*; Hytönen et al, 2008) are recommended. The prognosis of erythema migrans is good.

For facial palsy, the drug of choice is doxycycline, and alternative options are ceftriaxone, cefotaxime or penicillin G, as above. For other forms of neuroborreliosis, carditis or other organ involvements, the first choice is ceftriaxone 2 g/day for 14 days. Alternative drugs are cefotaxime and penicillin G (Schnarr et al, 2006*). For the treatment of European patients with neuroborreliosis, oral doxycycline has been shown to be as efficient as intravenous ceftriaxone.

For arthritis or acrodermatitis, the treatment options vary. Ceftriaxone 2 g/day for 14–21 days or doxycycline 200 mg/day for 1–2 months can be used (Schnarr et al, 2006*; Hytönen et al, 2008). An alternative choice is amoxicillin as above, cefotaxime 2 g three times a day IV or penicillin G 5×10^6 IV four times a day, for 14–21 days (Schnarr et al, 2006*). The arthritis often settles within 3 months from the onset of treatment. If the arthritis persists, another course with unrelated antibiotics can be used (Puéchal and Sibilia, 2009). Besides antibiotics, patients need analgesics and anti-inflammatory drugs. The administration of systemic or intra-articular glucocorticoids is controversial, because they may impair the eradication of the spirochete (Steere and Angelis, 2006). Physiotherapy is often of benefit, especially for knee synovitis. If the arthritis persists after adequate antibiotic therapy, synovectomy can be considered. Use of disease-modifying antirheumatic drugs, such as hydroxychloroquine, sulfasalazine and methotrexate, is an option in a resistant case with active joint inflammation (Franssila and Hedman, 2006*). A consensus has emerged that repeated courses of antibiotic therapy are not indicated for persistent subjective symptoms, such as musculoskeletal pain following Lyme

disease (Puéchal and Sibilia, 2009). The patient should be thoroughly examined for other medical conditions that might explain the symptoms, and treated accordingly.

3 Viral causes of arthritis

A large number of viruses are well-recognised causes of inflammatory arthritis. Acute onset polyarthritis should always raise the suspicion for viral arthritis. Over the past few years the epidemiology of viral arthritis has swiftly changed, with several epidemics of arbovirus related arthritis being increasingly recognized in different parts of the globe. With increase in the frequency of trans-continental travel, these viruses have transcended geographical boundaries and have affected various populations.

3.1 Parvovirus

Human parvovirus B19 is a small non-enveloped single-stranded DNA virus, which ~~only~~ generally replicates in erythrocyte precursors. Transmission of infection occurs via a respiratory route, through blood products, and vertically from mother to foetus. About half of the infections are asymptomatic. Parvovirus B19 is a common viral infection affecting predominantly children, in whom it causes erythema infectiosum ('Fifth disease'), a febrile exanthema characterised by a 'slapped cheek' rash with or without joint symptoms. The rash is typical, and can be easily diagnosed. In adults, its manifestations are more protean, including symptoms such as aplastic anaemia, thrombocytopenia, pancytopenia, hepatitis, myocarditis, myositis and symptoms of the central nervous system. Arthritis or arthralgia occurs in about 8% of juvenile and 60% of young adult patients (Franssila and Hedman, 2006*). During pregnancy, the infection can cause hydrops fetalis and death of the foetus.

3.1.1 Clinical picture and diagnosis of parvovirus arthritis

Children generally present with an asymmetric large-joint oligoarthritis, commonly the knee. Adults have a rheumatoid arthritis like symmetrical, small joint predominant arthritis involving the small joints of hands. (Marks et al, 2016). The arthritis is more common in female than in male patients. It is transient and usually subsides within 3 weeks, without permanent damage. In about 20% of patients, usually women, the arthritis/arthralgia persists for months. Chronic inflammatory arthritis is rarely seen with parvovirus arthritis. (Danda et al. 2010).

The diagnosis of parvovirus infection is made by serology, where the presence of IgM class parvovirus antibodies indicates an infection within 3 months. As most people have acquired parvovirus infection in childhood, the presence of IgG class antibodies is common and, in the absence of IgM class antibodies, is not of diagnostic aid. The patients can be transiently seropositive for rheumatoid factor, antineutrophil cytoplasmic antibodies and have various autoantibodies, which can make the differential diagnosis between parvovirus arthritis and other arthritides complicated. Sometimes, patients may also have thrombocytopenia, thus resembling systemic lupus erythematosus. The clinical picture of systemic lupus erythematosus and parvovirus infection can be very

similar; furthermore, non-specific anti-parvovirus antibodies can be produced by a patient with established lupus. Parvovirus infection is a rare cause of the development or flare-up of systemic lupus erythematosus. Other autoimmune diseases like rheumatoid arthritis, systemic sclerosis, myositis, vasculitis, juvenile idiopathic arthritis and chronic fatigue syndrome have been described to be triggered by or associated with parvovirus B19 infection, but these ideas lack strong supporting evidence.

Parvoviral B19 DNA has been detected in synovial fluid samples in some patients with early synovitis or with chronic RA. The role of parvovirus in triggering chronic arthritis or autoimmune disease has been discussed for years. It seems, however, that the progression of parvovirus arthritis to chronic RA, systemic lupus erythematosus or vasculitis is extremely rare (Franssila and Hedman, 2006*).

3.1.2 Treatment of parvovirus arthritis

Erythema infectiosum does not usually require any treatment. The arthralgia/arthritis can be treated with NSAIDs, if severe. The prognosis is usually good.

Interestingly, about 50% of both juvenile and adult patients with various rheumatic diseases and positive antiphospholipid antibodies have evidence of persisting parvovirus B19 infection. There are reports of a small number of patients with juvenile arthritis resistant to all previous drugs where the use of intravenous gammaglobulin therapy resulted in loss of parvovirus B19 viraemia and good clinical response.

3.2 Rubella

Rubella virus is a single-stranded RNA-containing virus. The most common manifestation of the infection is rash, preceded about 6 days previously by lymphadenopathy.

3.2.1 Clinical picture and diagnosis of rubella arthritis

Arthritis and arthralgia are uncommon in children and in men, but occur in about 50% of women, soon after the onset of the rash. Symmetrical polyarthritis involving the metacarpophalangeal and proximal interphalangeal joints of hands, followed by wrists, knees, ankles and elbows is common. The arthritis is self-limiting, usually lasting for a maximum of 3 weeks. Sometimes, a prolonged or relapsing course can occur. Rubella infection can be prevented by vaccination with attenuated living rubella vaccines. Vaccination can also induce a similar form of arthritis in women, thought to be due to immune complexes (Franssila and Hedman, 2006*).

The routine laboratory diagnosis is based on the detection of antirubella antibodies in the serum. Detection of antirubella IgM in combination with IgG seroconversion or detection of a rise in rubella-specific IgG in paired serum samples indicates acute infection. Recent primary rubella, remote rubella infection, reinfection and persistent rubella IgM reactivity may be differentiated by measuring rubella-specific IgG avidity (Franssila and Hedman, 2006*).

3.2.2 Treatment of rubella arthritis

Rubella arthritis is usually short-lived and can be managed by symptomatic drugs—for example, NSAIDs. In the rare case of persistent rubella arthropathy, intravenous immunoglobulin therapy may be effective.

3.3 Hepatitis B

HBV is a double stranded DNA virus belonging to Hepadnaviridae family, and well known for its extra-hepatic association. Following transmission vertically, sexually, or through blood-borne contact, about 95% of adults mount an immune response resulting in clearance of the virus. Arthritis in HBV, seen both in the prodromal phase and chronic infection, occurs as a result of formation and deposition of immune complexes containing viral antigens.

3.3.1 Clinical picture and diagnosis

In the acute phase arthritis can be the only presenting feature, occurring as part of serum sickness. Symmetrical polyarthritis, resembling rheumatoid arthritis, affecting small and large joints is the usual manifestation in prodromal phase of infection. Arthritis lasts for days to months, resolving with the onset of jaundice. A quarter of patients with chronic infection complain of joint symptoms, though severe joint damage is uncommon. Association of immune complex deposition syndromes like cryoglobulinaemia and polyarteritis nodosa should be considered in patients presenting with chronic arthritis. Serologic tests for hepatitis B surface antigen (HBsAg) and hepatitis B core antibody (anti-HBc) IgM are required for diagnosing acute hepatitis B infection. Liver function tests including liver enzymes, direct serum bilirubin, albumin and measurement of international normalized ratio (INR) should be done in all patients. Quantification of HBV DNA gives an estimate of level of infectivity. Chronic active HBV infection is categorized into HBeAg positive and HBeAg negative disease. Rheumatoid factor can be positive in 25% of patients, while C3 and C4 may be low in around 40% of patients due to immune-complex mediated process.

3.3.2 Treatment

A detail discussion on this topic is not within the purview of this chapter. Anti-viral therapies like lamivudine, adefovir, tenofovir and entecavir, and recombinant interferon-alpha and its pegylated form, are the commonly used therapies, which cause suppression of HBV replication. Use of non-biologic DMARDs in HBsAg positive or negative and anti-HBc positive patients may increase the risk of reactivation. In patients with low risk of reactivation non-biologic DMARD usage is relatively safe. Risk of reactivation of HBV during therapy with biologic DMARDs increases. Anti-viral prophylaxis should be considered in patients requiring DMARDs or corticosteroids. (Felis-Giemza et al, 2015). According to the 2012 update of 2008 ACR recommendations for treatment of RA none of the biologic therapies are recommended in untreated chronic hepatitis B or those with treated chronic hepatitis B with Child Pugh class B and higher. (Singh et al, 2012)

3.4 Hepatitis C

HCV is a linear, small size, single stranded RNA virus belonging to the family of *Flaviviridae*. It is a blood-borne virus, which usually gets transmitted as a result of poor sterilization of medical devices and unscreened blood products. Vertical and sexual transmission is also described. HCV is a hepato- and lymphotropic agent, which leads to chronic infection in 70-80% of affected patients. HCV causes arthritis by direct invasion of synovium, autoimmune response to virus in the synovium and immune complex or cryoglobulin deposition.

3.4.1 Clinical picture and diagnosis

Rheumatological manifestations are one of the most frequent extra-hepatic manifestations of HCV. There has been a renewed interest of late in association of HCV with autoimmune diseases like SLE, Sjögren's syndrome, rheumatoid arthritis, polyarteritis nodosa and antiphospholipid syndrome. Arthralgia (mono-, oligo- and polyarticular) is a frequent symptom. HCV related arthritis can have similar presentation as rheumatoid arthritis, thus making it difficult to distinguish both. RF positivity has been noted in 54-80% of patients with HCV-related arthritis, often in high titres. The course of arthritis, however, is less aggressive in HCV patients as compared to RA. Other manifestations include paraesthesia, myalgia, pruritus, sicca symptoms and fibromyalgia. Presence of HCV in a patient with arthritis should raise suspicion of HCV related arthropathy. Serological tests to detect HCV antibodies and molecular tests to quantify HCV RNA remain the mainstay of diagnosis. Identifying the genotype is useful for predicting response and determining duration of interferon therapy.

3.4.2 Treatment

Conservative management with analgesics and NSAIDs is recommended for patients with mild arthritis. Patients not responding to NSAIDs may be initiated on low dose steroid therapy. As there are no consensus treatment guidelines to treat HCV with arthritis, management should be individualized. Ironically, interferon alpha is known to precipitate autoimmune diseases.

HCV infection with concomitant RA

Use of DMARDs is indicated in patients with RA and concomitant HCV infection. A step-wise approach, starting with non-biologic DMARDs, followed by biologic DMARDs in those unresponsive to initial therapy is preferred practice. According to the 2012 ACR update of 2008 recommendations for the use of DMARDs in RA, Etanercept is the recommended biologic for RA with concomitant HCV infection. Methotrexate is contraindicated in all patients with Child-Pugh class A, B or C; Sulphasalazine is contraindicated in patients with Child-Pugh class B or C and Hydroxychloroquine is contraindicated in patients with Child-Pugh class C.

HCV infection with cryoglobulinaemia

A combination of pegylated interferon and ribavirin is the current standard antiviral treatment in this situation. Patients with severe disease seem to benefit with antiviral therapy along with Rituximab. Plasma exchange is useful for rapidly removing cryoglobulins and immune complexes.

HTLV-1 associated arthritis

HTLV-1 is a retrovirus known to cause peripheral, symmetric, polyarthritis involving small and large joints, akin to rheumatoid arthritis. Rheumatoid factor can be positive in these patients. Patients are predisposed to T cell leukaemia.

3.5 Alphavirus arthritis

Alphaviruses belong to a group of arboviruses and share the common feature of transmission by arthropod vectors. Alphaviruses are spherical small RNA-containing viruses with a potential to induce arthritis, fever, fatigue and rash. The spectrum of clinical symptoms associated with alphavirus infections is wide, from severe haemorrhagic symptoms to paraesthesia and glomerulonephritis (table 7).

Table 7 Viruses related to articular symptoms. (Modified from Laine et al, J Int Med 2004;256:457–71)

Virus	Clinical features	Epidemiological area
Chikungunya	Fever, rash, myalgia, arthralgia/arthritis, chronic joint pain, haemorrhagic symptoms, paraesthesias	Africa, India, South East Asia, West Pacific, sporadic in Europe, USA
Mayaro	Fever, rash, myalgia, arthralgia/arthritis, chronic joint pain, haemorrhagic symptoms	South America
O'nyong-nyong	Fever, rash, myalgia, arthralgia/arthritis, chronic joint pain, haemorrhagic symptoms, paraesthesias	Central and East Africa
Barmah Forest	Fever, rash, myalgia, arthralgia/arthritis	Australia
Igbo Ora	Fever, rash, myalgia, arthralgia	Ivory Coast
Ross River	Fever, rash, polyarthritis, chronic arthralgia, paraesthesias, glomerulonephritis	Australia, West Pacific
Sindbis	Fever, rash, arthralgia/arthritis, paraesthesias	Europe, Africa, Australia, Asia, Philippines
- Ockelbo	Fever, rash, arthralgia/arthritis, chronic joint pain, paraesthesias	Sweden, Norway
- Pogosta	Fever, rash, arthralgia/arthritis, chronic arthritis	Finland
- Karelian fever	Fever, rash, arthralgia	Russia
- Dengue	Fever, rash, severe myalgia, polyarthralgia, haemorrhagic symptoms	India, South East Asia, Africa, Latin America
- Zika	Fever, maculopapular rash, muscle aches, arthralgia	Africa, South East Asia, Americas

In Northern Europe, milder forms of disease induced by alphaviruses belonging to the Sindbis group have been described in several countries. In Finland, this mosquito-borne viral disease is called Pogosta disease, in Sweden, Ockelbo disease, and in Russian Karelia it is called Karelian fever.

3.5.1 Chikungunya virus

The most severe form of arbovirus-induced arthritis is caused by Chikungunya virus (CHIKV), belonging to the family *Togaviridae*. Following its initial isolation in Tanzania in 1952 the virus was locally confined and of low intensity. Since 2005, it has caused a large outbreak in the southwest Indian Ocean islands and the infection has spread to India, causing a large epidemic with more than 1.5 million people infected (Taubitz et al, 2007). As tourism is expanding, European and US travellers returning home from these areas have been described with severe arthritis and tenosynovitis caused by the Chikungunya virus (Taubitz et al, 2007). The first cases of CHIKV in the Americas were described in 2013. Chikungunya arthritis has also been described in Europe in patients who have not travelled. CHIKV is globally distributed in over 60 countries and continues to be endemic in Africa, India and several Southeast Asian countries and Latin America.

3.5.1.1 Clinical picture and diagnosis of CHIKV

The clinical picture of Chikungunya virus infection is biphasic. Acute infection (< 10 days) manifests as fever, arthralgia, back pain and headache. Less common clinical features include skin rashes, oral ulcerations, hyperpigmentation and exfoliative dermatitis. Low to high-grade fever lasts for 3-5 days. Symmetrical polyarthralgia involving distal joints, hands, wrists and ankles develops 2-5 days following onset of fever. Peri-articular oedema or swelling can be seen in 32-95% of patients. Oedema of the face and periauricular tissues is characteristic. Generally acute CHIKV infection resolves without any sequelae. Chronic rheumatologic manifestations, including polyarthralgia or arthritis, multiple tendinitis, tenosynovitis, enthesopathies, carpal tunnel syndrome, classical rheumatoid arthritis, cryoglobulinaemia and psoriatic arthritis, however, can occur in a small group of patients. Detection of viral antigen, viral nucleic acid, anti-CHIKV IgM and IgG antibodies and viral culture continue to be the mainstay of diagnostic tests. Anti-CHIKV IgM are elevated after 10 days of infection and remain elevated for 3-6 months. Reverse transcription polymerase chain reaction (RT-PCR) and real time loop-mediated isothermal amplification (RT-LAMP) methods aid in early diagnosis of CHIKV infection. (Mathew AJ et al, 2016)

3.5.1.2 Treatment

Treatment of acute infection is mainly conservative, with analgesics, antipyretics and NSAIDs. After the initial viraemic febrile period is over, low dose steroid with rapid tapering and withdrawal by 4-6 weeks is effective and safe for acute CHIKV infection. Hydroxychloroquine (HCQ) has been reported in few studies to be effective in acute infections. HCQ also has anti-viral properties. However, anti-inflammatory action of HCQ takes months

to act, and hence, its use in such self-limiting disease is controversial. Development of vaccines is still in infancy, and requires testing in clinical trials. DMARDs have been tried in chronic infections, with varied success.

3.5.2 Other alphaviruses

Sindbis virus-induced diseases in Northern Europe typically occur in late summer or early autumn. The incubation time is short (2–10 days), after which the onset of arthritis is usually sudden. The arthritis in Pogosta disease is often oligoarticular (ankle, knee, wrist, fingers, especially metacarpophalangeal joints) and occurs usually in the summer and early autumn. Other features are fatigue and maculopapular rash, often itchy, present in the majority of patients. The rash appears 3–4 days after the onset of illness, and disappears after a few days. Other systemic symptoms include fever, muscle pain, malaise, headache, nausea, and retro-orbital pain. Symptoms common to all alphavirus infections include rhinorrhoea, sore throat, marked lethargy and backache. The arthritis is usually transient with migratory arthralgia in the small joints of hands, feet, wrists and ankles, often accompanied by generalised myalgia. In about half of patients the recovery from arthritis can take more than 1 month, even more than 12 months in few cases, but a complete recovery is the rule (Laine et al, 2004). Men and women are affected with similar frequency. Clinical disease is less common in children, who often have subclinical infection. Some alphavirus infections affecting populations outside Europe (see table 7) can induce petechiae, bleeding and neurological symptoms, but the European Sindbis virus infections are milder.

The diagnosis of alphavirus infection is based on history (travelling in tropical areas, walking in forests in summer/early autumn) or on clinical picture (rash and arthritis) and is confirmed by serology.

Treatment is symptomatic, but acetyl salicylic acid is to be avoided if there is a suspicion of a haemorrhagic disease. Prevention is important by the use of mosquito repellents, mosquito nets in the tropics and appropriate clothing.

3.4 HIV and arthritis

Patients infected with HIV have an increased frequency of musculoskeletal complaints (Reveille and Williams, 2006*). In the pathogenesis of arthritides, direct spreading of HIV to the joints, immune response of the host to the infection and infection of the host with pathogens known to be capable of triggering reactive arthritis, especially in HLA-B27-positive subjects (chlamydia, salmonella, yersinia, shigella, campylobacter), contribute to the development of arthritis in this setting.

There are definite geographical variations in the prevalence and clinical spectrum of musculoskeletal manifestations of HIV infection in reports from different centres. This has been thought to be probably secondary to several factors, such as patient selection, ethnic background, risk factors, stage of HIV infection, use of specific highly active antiretroviral therapy (HAART), among others. Arthralgia occurs in 5% of patients with HIV infection. The musculoskeletal symptoms can be divided into three subgroups: those associated directly

with the HIV infection, those occurring more frequently in HIV-positive individuals, at least partially associated with increased risk of infection, and those as a result of HIV treatment.

Septic arthritis due to the usual infectious agents is not increased in patients with HIV, but musculoskeletal infections due to atypical mycobacteria are increased. Mycobacteria most frequently causing septic arthritis or osteomyelitis include *Mycobacterium avium intracellulare*, *M. kansasii*, *M. haemophilum*, *M. terrae* and *M. fortuitum* (Reveille and Williams, 2006*). These induce systemic infection, and often, infection of several joints or skeletal sites. Cutaneous lesions (nodules, ulcers, draining sinus tracts) occur frequently. These infections occur late in the course of HIV, as do fungal infections, which also can cause septic arthritis. A patient with joints infected with opportunistic infection should be examined for the presence of HIV antibodies.

3.4.1 HIV arthritis

HIV infection can present with a wide variety of musculoskeletal manifestations including arthralgia, painful articular syndrome (self-limiting syndrome lasting less than 24 hours), HIV associated oligoarthritis and ReA like presentation. Acute HIV infection is associated with arthritis, which resembles other viral arthritides. Infective joint complications are also frequently seen in the African patients with AIDS, in whom AIDS is the leading cause of aseptic arthritis (60% of the cases). The disease does not meet the classification criteria for spondyloarthritis. It is typically oligoarticular, predominantly in the lower extremities, and lasts for <6 weeks. Synovial fluid, if obtained for analysis, is non-inflammatory and sterile for bacteria. There is no increased association with HLA-B27, mainly because this HLA type is not present in many African populations. The arthritis is usually self-limiting, and can be treated with NSAIDs. In the more severe forms, low-dose glucocorticoids, hydroxychloroquine or sulfasalazine can be used. Previously, HIV-infected patients often developed spondyloarthritis or severe psoriasis-like skin disease and also psoriatic arthritis. The use of HAART is effective in the treatment of HIV infection and also the associated psoriasis and arthritis.

3.4.2 Reactive arthritis in HIV-infected patients

Reactive arthritis is observed in 5–10%, psoriatic arthritis in 1–6% and undifferentiated spondyloarthritis in 3–11% of patients with AIDS. Clinical features in the phenotypes of arthritides differ between African and Western patients, those in the West having more typical reactive arthritis. The clinical picture is classical of reactive arthritis and spondyloarthritis with oligoarticular pattern, enthesitis and sausage toes/fingers. Mucocutaneous complications (keratoderma blenorrhagica and circinate balanitis) are common. The disease is associated with HLA-B27. Treatment is similar to that for reactive arthritis in general, starting with NSAIDs. In more severe or prolonged disease, sulfasalazine is the recommended drug, but hydroxychloroquine can also be tried. Methotrexate and cyclosporine, owing to their immunosuppressive effect, theoretically might enhance the HIV load, but can be used if the viral load and the number of CD4+ cells are monitored. Skin lesions in reactive arthritis and psoriatic arthritis respond also to etretinate (Reveille and Williams, 2006*). Although biological

drugs are not officially recommended and not indicated for HIV-related diseases, there are some case reports of the use of tumour necrosis factor (TNF)-blocking agents in a patient with severe arthritis/skin disease, with good clinical response and without any major increase in the risk of infections or progression of immunosuppression in the short term.

3.4.3 Arthritis in the HAART era

The availability of HAART has made a great change in the well-being and prognosis of patients infected with HIV. While the complications of HIV infection are effectively suppressed by the treatment, the return of immunocompetent cells has been associated with de novo appearing autoimmune phenomena. A new non-infectious immune reconstitution syndrome has been described in patients receiving HAART. Patients with this syndrome develop an autoimmune disease, mostly presenting as sarcoidosis or systemic lupus erythematosus-like disease, or a non-systemic autoimmune syndrome, usually thyroid disease (Calabrese et al, 2005).

Several other musculoskeletal symptoms are commonly noted. Diffuse myopathy, muscular pain, raised muscle enzyme levels, even rhabdomyolysis, systemic lupus erythematosus, sarcoidosis, osteopenia and osteoporosis, and avascular necrosis of bone have been reported with increasing frequency in patients treated with antiviral drugs. These adverse events have been linked to various treatments, especially protease inhibitors. At the same time, there has been a great shift in the spectrum of associated diseases as compared to patients who have never received HAART. The development of reactive arthritis, psoriasis arthritis and mono/oligo/polyarthritis and myositis have been definitely declining in patients receiving HAART (Calabrese et al, 2005).

4 Role of infections in the aetiology of chronic rheumatic diseases

4.1 Whipple's disease

Whipple's disease is rare, with protean manifestations ranging from arthralgia and malabsorption to neurological symptoms. If untreated, the disease can be fatal. Whipple's disease was first described by George Whipple in 1907 but the first successful culture of the causative bacterium (classified as an actinomycete), *Tropheryma whippelii*, took place nearly 100 years later in 2000. The organism was initially named *Trophynema whippelii* but the name was subsequently changed to *Tropheryma whippelii*. The name comes from Greek words *troph*i (food) and *eryma* (barrier) referring to the malabsorption which is often associated with the disease.

4.1.1 Pathogenesis

There are no valid estimates of the prevalence of Whipple's disease. Only about 1000 cases have been reported, mostly in middle-aged white men, but considering the assumed ubiquitous prevalence of the causative organism and the difficulty of diagnosis, the true prevalence might be higher. In post mortem studies the prevalence has been described as <0.1%. The pathogenic bacteria *T. whippelii* appears to be present ubiquitously in the

environment but its exact source is not established. The presence of *T. whipplei* has been demonstrated by PCR in human stool, and an association with *Giardia lamblia* infection has been reported. It has been suggested that transmission of *T. whipplei* takes place through faecal-oral transmission and it is possible that significantly more people are exposed to *T. whipplei* than those who actually develop the disease. Thus, genetic factors and undefined subtle defects in cellular immunity, perhaps specific for *T. whipplei*, may play a role in its pathogenesis (Marth and Raoult, 2003; Fenollar et al, 2007*).

4.1.2 Clinical picture

The typical patient is a middle-aged white man who presents with joint symptoms, malabsorption and wasting. The disease can, however, occur at all ages and it should be noted that about 15% of patients do not have the classic signs and symptoms. In those cases the diagnosis may be difficult. Whipple's disease has two stages: the prodromal stage and the steady state. The prodromal stage is characterised by protean, non-specific manifestations—in particular, arthralgia and arthritis. Weight loss and diarrhoea are characteristic of the steady state but several other symptoms can also occur. The length of the prodromal stage can be quite long, with an average duration of 6 years. It is noteworthy that if the patient has received immunosuppressive therapy, such as glucocorticoids or anti-TNF blockers, the progression of the disease may be faster.

Joint involvement is common and has been reported in 65–90% of patients with classic Whipple's disease. Arthropathy is also commonly the first manifestation of Whipple's disease. The most common form of arthropathy is a migratory intermittent non-destructive oligoarthritis or polyarthritis. Destructive arthritis resembling seronegative RA can also occur but it is rarer. In rare cases spondyloarthropathy and hypertrophic osteoarthropathy have been described. In a middle-aged man with unexplained intermittent polyarthritis, Whipple's disease should be considered as a possibility.

The most common gastrointestinal manifestation is weight loss (90% of patients), which may be associated with diarrhoea. Occult bleeding from the intestinal tract has been reported in 20–30% of patients. In addition, abdominal pain, hepatosplenomegaly and hepatitis may be seen.

Neurological symptoms occur relatively commonly in association with Whipple's disease. They have been reported in 6–63% of patients with classic Whipple's disease, but in a small series of 11 patients' central nervous system involvement was described in 10, based on autopsy findings. The neurological manifestations vary and range from commonly occurring cognitive changes to dementia. Depression and personality changes are seen in about half of patients who have neurological involvement. Supranuclear ophthalmoplegia, myoclonus and hypothalamic involvement have been described. The prognosis of patients who have neurological involvement is poor with significant mortality and presence of persistent neurological sequelae.

Cardiac involvement is also relatively common. Cardiac murmurs, insufficiency of aortic or mitral valve as well as blood culture negative endocarditis have been described.

Other commonly (>30% of cases) occurring symptoms include fever, lymphadenopathy, hyperpigmentation, peripheral oedema and hypotension.

4.1.3 *Diagnosis*

As the manifestations of the disease vary a high degree of suspicion is required to make the diagnosis. Symptoms, such as malabsorption, wasting and abdominal symptoms occurring in association with atypical seronegative arthritis should suggest a diagnosis of Whipple's disease. Histological examination and periodic acid–Schiff (PAS) staining of biopsy samples from the duodenum or jejunum should be obtained to confirm the diagnosis. PCR can be used to complement the PAS staining. PCR can also be used to detect *T. whipplei* in other body tissues and fluids. Humoral response cannot be used as a diagnostic tool in Whipple's disease.

4.1.4 *Treatment*

Initiation of antibiotic treatment leads to rapid resolution of symptoms in many patients. Diarrhoea and fever may resolve in 1 week and arthropathy in a few weeks. Tetracycline was previously used as a first-line treatment, but the relapse rates were high. Thus, antibiotics which can effectively cross the blood–brain barrier are favoured these days for treatment. Recommended treatment is to use the combination of trimethoprim (160 mg) with sulfamethoxazole (800 mg) twice a day for 1–2 years. The oral treatment should be preceded, especially in severely ill patients, by parenteral administration of a 2-week course of ceftriaxone (2 g daily) or streptomycin (1 g/day) combined with penicillin G (1.2×10^6 U/day). However, lack of clinical response as well as relapses have been reported also with this regimen (Marth and Raoult, 2003; Fenollar et al, 2007*).

4.2 **Fungal arthritis**

Fungal causes of arthritis are very uncommon. Haematogenous dissemination or direct inoculation following injury, surgery and intra-articular injections are the common modes of spread. Presentation can be acute mono- or polyarticular in 60% of patients or indolent. Large, weight-bearing joints are commonly affected. Isolation of the organism, along with imaging and bone scan is the preferred method of diagnosis. Early diagnosis of such arthritis has been attempted by PCR.

4.3 **Is RA caused by infection?**

In addition to genetic susceptibility, environmental factors have been suggested to play a role in the development of RA. Among those, infections have been widely suspected, though a definite association is lacking. Epstein Barr virus, Parvovirus and rubella have been commonly suspected viral candidates. The suspected mechanisms range from direct infection by mycobacteria, streptococcus or mycoplasma to

immunological cross-reactivity between bacterial antigens (eg, *Porphyromonas gingivalis*, a bacterium associated with periodontal disease) and the host. In about 20% of patients with early RA, there is serological evidence of some recent infection. There is not a single putative microbe, but several microbes may be able to induce joint disease in a susceptible patient.

4.3.1 Epstein–Barr virus infection

Epstein–Barr virus (EBV) is a tumorigenic herpesvirus that infects over 90% of the adult population world-wide. The virus persists for a person's entire lifetime without causing overt disease, and the persistence is sustained by a fine balance between the host immune system and the virus. This common infection has been one of the infectious candidates for RA for several years. The virus affects B cell immunity inducing polyclonal activation of B cells and production of autoantibodies, including rheumatoid factor, anti-DNA antibodies, antiphospholipid antibodies and anti-cyclic citrullinated peptide antibodies. EBV can directly infect synovial cells. Patients with chronic RA have higher levels of anti-EBV antibodies than healthy controls. In addition, EBV-specific cytotoxic T cell function, which is needed for the control of chronic infection, is defective in patients; this probably causes the observed increase in viral load (Leirisalo Repo, 2005a). Although there is no good evidence in favour of the primary infection as a trigger of subsequent RA, based on the above-mentioned immune aberrations, EBV would be a good candidate to trigger chronic immune complex disease.

EBV, cytomegalovirus and parvovirus B19 have been found to persist in a latent form in the synovial fluid/synovial tissue of patients with RA and psoriatic arthritis, but less frequently in those with reactive arthritis. This can be interpreted either as evidence of the primary role of these viruses in autoimmune arthritis or as indicating that the circulating inflammatory cells harbouring the viral DNA of persisting viruses migrate as innocent bystanders to the inflamed synovium.

In summary, there is some epidemiological evidence referring to the possibility that patients who develop first manifestations of RA might have had various infections close to the onset of arthritis. The role of persisting viral infections as a cause of RA needs further confirmation.

4.4 Is ankylosing spondylitis caused by infection?

4.4.1 Bacteria and ankylosing spondylitis

There is indirect evidence that previous bacterial infection can be associated with the later development of ankylosing spondylitis. This is based on the fact that a minority of patients with acute reactive arthritis, especially if they possess HLA-B27 develop the disease 10–20 years after the initial infection. Furthermore, there is increasing evidence for the role of the gut microbiota in the maintenance of joint symptoms in patients with chronic spondyloarthritides or ankylosing spondylitis.

About 10–20% of patients with chronic inflammatory bowel disease (IBD) develop a peripheral arthritis at some time during the course of their disease, and ankylosing spondylitis has been reported in between 5% and 10% of patients with IBD. HLA-B27-positive patients with IBD have an especially high risk of developing ankylosing spondylitis. Although no specific microbes have been shown to be responsible, altered gut microbiota or dysbiosis, such as reported in patients with IBD, might be involved. *Klebsiella*, a microbe belonging to normal gut flora, has been previously suspected, especially in association with peripheral arthritis, but current evidence does not support this idea. Previous infection with *Chlamydia trachomatis* has also been linked to the subsequent development of sacroiliitis and ankylosing spondylitis. Also, flares of established ankylosing spondylitis, especially if there is acute peripheral arthritis, can be due to superimposed acute reactive arthritis associated with enteric and urogenital infections.

Urogenital infections may also contribute to chronic spondyloarthritis. Prostatitis has been shown to support the continuing joint/axial inflammation in chronic reactive arthritis and ankylosing spondylitis. These associations suggest a more thorough search is needed for microbes in patients with active ankylosing spondylitis—notably, in gut microbiota.

Environmental factors (most probably infections) have also been suggested to have a role in the severity and age of onset of ankylosing spondylitis. There are some reports that ankylosing spondylitis and related diseases are more severe in lower social classes with poorer hygiene.

In Mexico and China, ankylosing spondylitis starts at an earlier age and follows a more severe course than in Western Europe. In both the countries repeated bacterial infections of the gastrointestinal tract starting at a young age are frequent, especially in the lower socioeconomic strata. This indicates that persistent or repeated infection, most probably of the gut, may be an important contributor to the pathogenesis and also to the severity of ankylosing spondylitis.

In conclusion, the aetiology of ankylosing spondylitis is not known. The role of infectious agent(s) as a possible cause of ankylosing spondylitis has been suspected during the past 30–40 years. Indirect evidence for the role of infection comes from the following: (1) a proportion (20–35%) of patients with reactive arthritis, followed up prospectively for 20–25 years, developed sacroiliitis and ankylosing spondylitis; (2) chronic bacterial prostatitis has been associated with active ankylosing spondylitis, with treatment of the infection also suppressing the inflammatory back pain; (3) patients with active ankylosing spondylitis have a higher titre of IgA class antibodies than patients with low disease activity and (4) sacroiliitis and ankylosing spondylitis occur in patients with chronic IBD, such as ulcerative colitis and Crohn's disease.

4.5 Are other spondyloarthritides caused by infection?

Most patients with reactive arthritis recover, but about 15% continue to have chronic arthritis. Recurrent attacks of acute reactive arthritis occur in about 10–20% of patients with previous yersinia or salmonella arthritis, and are especially common in those with previous Chlamydia trachomatis induced arthritis. Factors determining the progression of acute reactive arthritis to chronic spondyloarthritis are incompletely understood, but persistent or recurrent urogenital infection or a chronic inflammatory focus in the gut may be a good explanation. The presence of yersinia and salmonella antigens has been demonstrated in synovial fluid cells or in synovial tissue of patients with reactive arthritis. Furthermore, yersinia structures have been shown to persist in submucosa of the gut, in lymph nodes and in the synovial fluid of patients with prolonged or chronic yersinia arthritis. Chlamydia trachomatis also persist in the infected host for months or even years. Reactive arthritis is the acute form of spondyloarthritis, whereas ankylosing spondylitis is at the other end of the spectrum. In reactive arthritis, infection has a definite triggering role, and for ankylosing spondylitis, the role of infection as one of the initiating factors or as a contributory factor in the flare-up has already been discussed. Most patients with chronic spondyloarthritis have no preceding known infection, but based on the similarities with other diseases of the same family, infection might have a role, at least in some patients. The finding of chlamydia antigens in the synovial tissue and/or peripheral blood mononuclear cells of some patients with chronic spondyloarthritis may suggest that chronic infection has a role in the development of chronic rheumatic disease (Carter et al, 2009*). Thus, infection has a definite role in the aetiology of acute reactive arthritis and probably contributes to the clinical activity or to the exacerbation of spondyloarthritides, in general.

SUMMARY POINTS

- Direct infection of a joint (septic arthritis) should be suspected in a patient with acute monoarthritis, usually in the lower limbs. Most patients have a contributing factor for the infection. The affected joint should be aspirated and the fluid should be analysed with Gram stain, bacterial culture and white blood cell count with differential. Bacterial cultures of blood, mucosa, wounds and skin lesions should be performed. Treatment with an intravenous antibiotic should be started immediately without waiting for microbiological verification.
- Reactive arthritis is characterised by oligoarthritis in a young or young adult patient, often preceded by enteritis or urethritis/cervicitis, often associated with extra-articular inflammatory signs and symptoms. Treatment is based on non-steroidal anti-inflammatory drugs and physiotherapy. Local glucocorticoid injections or systemic glucocorticoids can be used in severe cases. Antibiotics do not modify the course of the continuing arthritis. Most patients recover within the first 6 months, and 85% within 1 year.
- Lyme arthritis should be suspected in a patient with a history of a tick bite, especially if followed by erythema migrans. Arthritis is usually monoarticular, with predilection for the knee. The arthritis has a naturally waxing and waning course. The diagnosis of borreliosis can be confirmed by serology followed by immunoblot. Synovial fluid can be examined for borrelia by PCR. For treatment, antibiotics are used, usually doxycycline 200 mg/day for 1–2 months, or intravenous ceftriaxone for 14–21 days.
- Arthritis/arthritis is associated with several virus infections. The most important are parvovirus and rubella infections. Alphaviruses are a large family of viruses spread around the world capable of causing protean symptoms, including acute arthritis and prolonged joint pain. Diagnosis is based on clinical features supplemented by serology. Treatment is symptomatic and outcome is good.
- Patients with HIV infection may have septic or reactive forms of arthritis, and an increased frequency of psoriatic arthritis and spondyloarthritis. Increased load of infections, immunosuppression by HIV and direct effect of the HIV infection can contribute to the symptoms. With highly active antiretroviral therapy (HAART), patients have fewer opportunistic infections, but musculoskeletal symptoms are still often present.
- Whipple's disease is a rare chronic infection which manifests with generalised arthralgia and arthritis followed by a chronic phase, with diarrhoea, malabsorption, neurological and cardiac symptoms. The diagnosis is based on high clinical suspicion, and histological analysis of biopsy specimens from the duodenum or jejunum with PAS staining or PCR. Treatment is with long-term antibiotics.
- The role of various infections (especially Epstein–Barr virus, cytomegalovirus and parvovirus B19) as triggers of rheumatoid arthritis has been discussed for decades, with no clear positive answer.
- The aetiology of ankylosing spondylitis is not known, but chronic gut inflammation has been shown in a significant proportion of patients, leading to suspicion that altered gut microbiota play a part.

Infection and arthritis. Reactive arthritis - Lyme - Whipple - HIV - Viral arthritis - Septic arthritis

Ashish J Mathew, Debashish Danda, Hill Gaston

A previous version was coauthored by Maxime Breban, Riita Koivuniemi, Marjatta Leirisalo-Repo, Ben A. Dijkmans, Kari K. Eklund and Janneke Tekstra.

IN-DEPTH DISCUSSION I

**Reactive arthritis – treatment of acute and
prolonged/chronic arthritis**

Patients with acute reactive arthritis are most often treated with non-steroidal anti-inflammatory drugs as a first line-therapy, of which they often need high doses. Most patients have oligoarticular disease with arthritis predominantly affecting large joints of the lower limbs. Intra-articular injections with glucocorticoids are usually effective. In the case of a patient with fever, low back pain, hip/knee arthritis insufficiently responding to the above-mentioned therapeutic interventions, systemic use of prednisone/prednisolone is indicated. Compared with patients with rheumatoid arthritis, who usually respond to very low doses, patients with reactive arthritis need higher doses, eg. 40 mg prednisolone as starting dose. Physiotherapy, local cold, and use of appliances (crutches to alleviate pressure of inflamed hip/knee/ankle) are part of the routine treatment in severe cases.

Extra-articular symptoms are usually mild and disappear with time. There are no controlled studies concerning various treatment modalities. Enthesopathy and dactylitis respond to local corticosteroid injections. Keratoderma responds to topical glucocorticoids, but if the patient has systemic symptoms (fever), systemic glucocorticoids can be used. If the patient has balanitis, Chlamydia and Candida infections should be searched for and treated appropriately. If there is no infection, mild topical glucocorticoid ointment can be used for short periods of time. Conjunctivitis can be a sign of reactive arthritis but does not normally require treatment but, if symptomatic, topical vasoconstrictors may be used. About 5% of patients with reactive arthritis have more serious eye symptoms, usually acute anterior uveitis, but also keratitis or posterior uveitis have been described. Acute anterior uveitis is usually affecting only one eye, and the eye is painful, red, and the patient has photophobia. Such a patient should be referred immediately to an ophthalmologist to be treated with local glucocorticoids and mydriates.

The use of antibiotics to treat acute reactive arthritis has been extensively studied, and the results have been largely negative. The use of antibiotics is indicated in the case of symptomatic infection, eg. positive stool culture for salmonella, campylobacter, yersinia or shigella: for salmonella and yersinia infections, ciprofloxacin 750 mg twice a day for 10 days; for Shigella dysenteriae norfloxacin 400 mg twice a day or ciprofloxacin 500 mg twice a day for 5-10 days, and for campylobacter a macrolide antibiotic e.g. roxithromycin 150 mg twice a day for 10 days.

The use of antibiotics in reactive arthritis triggered by gastroenteritis does not shorten the duration of the arthritis. For Chlamydia trachomatis infection, both the patient and the sexual partner(s) should be treated with antibiotics (azithromycin 1 g as a single dose) irrespective of arthritis. For Chlamydia trachomatis induced arthritis, there is limited evidence that a prolonged use of tetracyclines might be effective for the arthritis (1).

The prognosis of a patient with reactive arthritis is usually good. In a previous Finnish study, the average duration of arthritis was 3-5 months, and about 15 % of patients developed chronic sequels or proceeded into chronic spondyloarthritis (2). Often, after objective recovery and with normal laboratory markers of

inflammation and absence of arthritis, the patients continue to have pain in the involved areas. Part of this pain can be explained to be due to enthesopathy, and part due to muscle wasting during the acute phase. Therefore, physiotherapy and encouragement of the patient for exercises are part of the therapeutic process.

About 15% of the patients proceed into a chronic spondyloarthritis. In some of them, the chronicity is a sequel of recurrent acute arthritides. In such patients, treatment with DMARDs has been tried, with varying effect. There is only limited information of the efficacy of such an approach. Sulfasalazine has been shown to be effective when used in chronic reactive arthritis (3). Methotrexate and leflunomide have also been used, but they are only of limited efficacy, analogous to what is seen in the peripheral arthritis of ankylosing spondylitis (4, 5). Biologicals are a new class of drugs shown to be effective in chronic HLA-B27 associated diseases such as in ankylosing spondylitis (6), chronic spondyloarthritis (7), psoriatic arthritis (8, 9). Interestingly, case reports of patients with severe acute reactive arthritis and chronic reactive arthritis have shown a rapid efficacy of infliximab in the patients (10, 11, 12), without any evidence of relapse of infection. Of the eye inflammatory symptoms, acute anterior uveitis usually heals within 3 months, but can recur, and some patients proceed into chronic eye inflammation, and can develop glaucoma or cataract either due to recurrent inflammation or to glucocorticoid therapies (13).

Antibiotics, especially tetracyclines have also been used for months in the very severe chronic cases, without any large controlled study. Carter et al. (14) reported a beneficial effect of a combination treatment with doxycycline and rifampicin or with roxithromycin and rifampicin, used for 6 months on patients with chronic spondyloarthritis (duration of the disease for 10 years) with evidence of persisting chlamydia in the body, compared with doxycycline as a single treatment.

As many of the patients with chronic spondyloarthritis proceed to ankylosing spondylitis, the therapy can be followed according the treatment options suggested for ankylosing spondylitis.

IN-DEPTH DISCUSSION II

Diagnosis and treatment of Lyme arthritis

Diagnosis of borrelia infection

As joint symptoms are common in the population, and ticks (and ticks infected with borrelia) are widely distributed, the patient history focussing on the previous tick bites, and possible erythema migrans are important in the clinical diagnosis. A travelling history is important, as in Europe, Lyme borreliosis is primarily caused by the three species (*Borrelia burgdorferi sensu stricto*, *B. afzelii* and *garinii*), while *B. burgdorferi sensu stricto* is the only human pathogenic species in the US (1). The clinical spectrum is different in patients infected with different borrelia species.

Erythema migrans develops in about 70% of the patients at the site of the tick bite. A red papule developing immediately at the site of the bite is not an indication of borrelia infection. The infection has an incubation time of a few days to one month, after which the skin lesion develops, starting as a red macula or papule that slowly expands. However, as indicated above, the skin manifestation is lacking in one third of the patients. Erythema migrans is so typical that its presence can be taken as an indication of borreliosis. In those who do not develop erythema migrans, antibody detection methods can be used. Detection of the causative agent by culture isolation and PCR is confined to special situations.

Serology The serological examination consists of a serological screening assay (a sensitive ELISA assay), supplemented in the event of positive or equivocal result, by a confirmatory assay (immunoblot). As the borrelia species differ between US and European infections, the US serological, immunoblot or PCR tests cannot be used in European patients. Recently various recombinant antigens for better accuracy in ELISA tests have been developed (2). For optimal diagnostics, a close collaboration and discussion between the clinician and the local laboratory is recommended. The frequency of positive serology depends on the detection methods used by the local laboratory, and on the timing of the infection. Borrelia antibodies of IgM class start to rise 2-4 weeks after infection, peak within 6-8 weeks after which the production is switched to IgG class. In early localized disease, the sensitivity of positive antibody response is 20-50%, and most of the antibodies are of IgM class. If borreliosis is strongly suspected, serological follow-up is recommended. In early disseminated disease, the sensitivity rises to 70-90%. The majority of patients with short disease duration have IgM class antibodies, while in those with long disease duration, the IgG class of antibodies predominant.

Patients with late disease (e.g. arthritis or acrodermatitis) are nearly always seropositive with IgG class antibodies (see 2). Thus, a positive IgM antibody and negative IgG antibody result speaks against late disease. IgM and IgG class antibodies can persist in some patients for many years, even after therapy. Serology cannot be used as an indication of the effect of antibiotic therapy. Furthermore, after clinically successful therapy, there is no need to treat raised antibody levels.

For confirmation of the preceding infection by immunoblot, use of recombinant antigens is recommended (2). There are differences between different tests with respect to the antibody binding patterns. Here, as with antibody tests, the tests used in the US and Europe differ and the European tests should be used for European patients. Patients with early disease have immune response restricted to only a few proteins, but patients with late disease (e.g. arthritis) have IgG antibodies to a broad spectrum of antigens.

Antigen detection Culture of borrelia is a time consuming method and has a low sensitivity, especially in body fluids. For synovial fluid, PCR is positive in 50-70% of the patients, while culture is very seldom positive (2).

Treatment of Lyme arthritis

In the US, arthritis is the most frequent manifestation of disseminated and chronic borreliosis, about 60% of the patients developing joint manifestations months to years after the tick bite (3). However, a survey among German physicians showed that about 25% of patients with Lyme borreliosis had arthritis (4). There are no internationally accepted guidelines on how to treat Lyme arthritis. Some experts use parenteral antibiotics (ceftriaxone 1 g twice a day for 14-21 days) as the first-line therapy. However, Schnarr et al. recommend as first choice doxycycline 200 mg/day for 30 days. An alternative choice is amoxicillin 500-750 mg three times/day for a child or a pregnant patient. In the case of failure of previous treatment, ceftriaxone 1 g twice a day i.v. for 14-21 days is recommended. Alternative choices are cefotaxime 2 g 3 times a day i.v. or penicillin G 5 million units 4 times a day, for 14-21 days (3).

The arthritis often resolves within 3 months of the onset of treatment. In resistant cases, antibiotics have been used for up to 3 months. Besides antibiotics, patients need analgesics and anti-inflammatory drugs. The administration of systemic or intra-articular corticosteroids is controversial, because the treatment may impair the eradication of the spirochete (5). Physiotherapy is often of benefit, especially in the case of knee synovitis. The prognosis of arthritis is usually good, about 10% of untreated patients with arthritis recover per year. The majority of the patients respond to the antibiotic treatment (6). If the arthritis persists after adequate antibiotic therapy, synovectomy can be considered. Use of disease-modifying antirheumatic drugs is an option in the resistant case with active joint inflammation.

What to do, if the arthritis continues?

If the objective symptoms and signs persist for more than 1 year after adequate antibiotic therapy, the patient is considered to have treatment-resistant Lyme disease (3). However care must be taken in these cases to re-evaluate the evidence for Lyme disease to ensure that there is some certainty about the diagnosis and hence that the condition is definitely treatment-resistant. If persistent infection (positive PCR in the synovial fluid/synovial membrane, or in rare cases, positive borrelia culture) is demonstrated, the recommendation is to aim at eradication of the microbe (3). This includes switching from oral to parenteral antibiotics. There are

no controlled studies and the treatment options are usually based on case reports or on small open series of treated patients. Based on experience on 135 US patients with Lyme arthritis treated with various protocols, Steere and Angelis (5) propose a step-wise approach to the diagnosis and treatment of the patients with antibiotic-refractory arthritis (Figure 1).

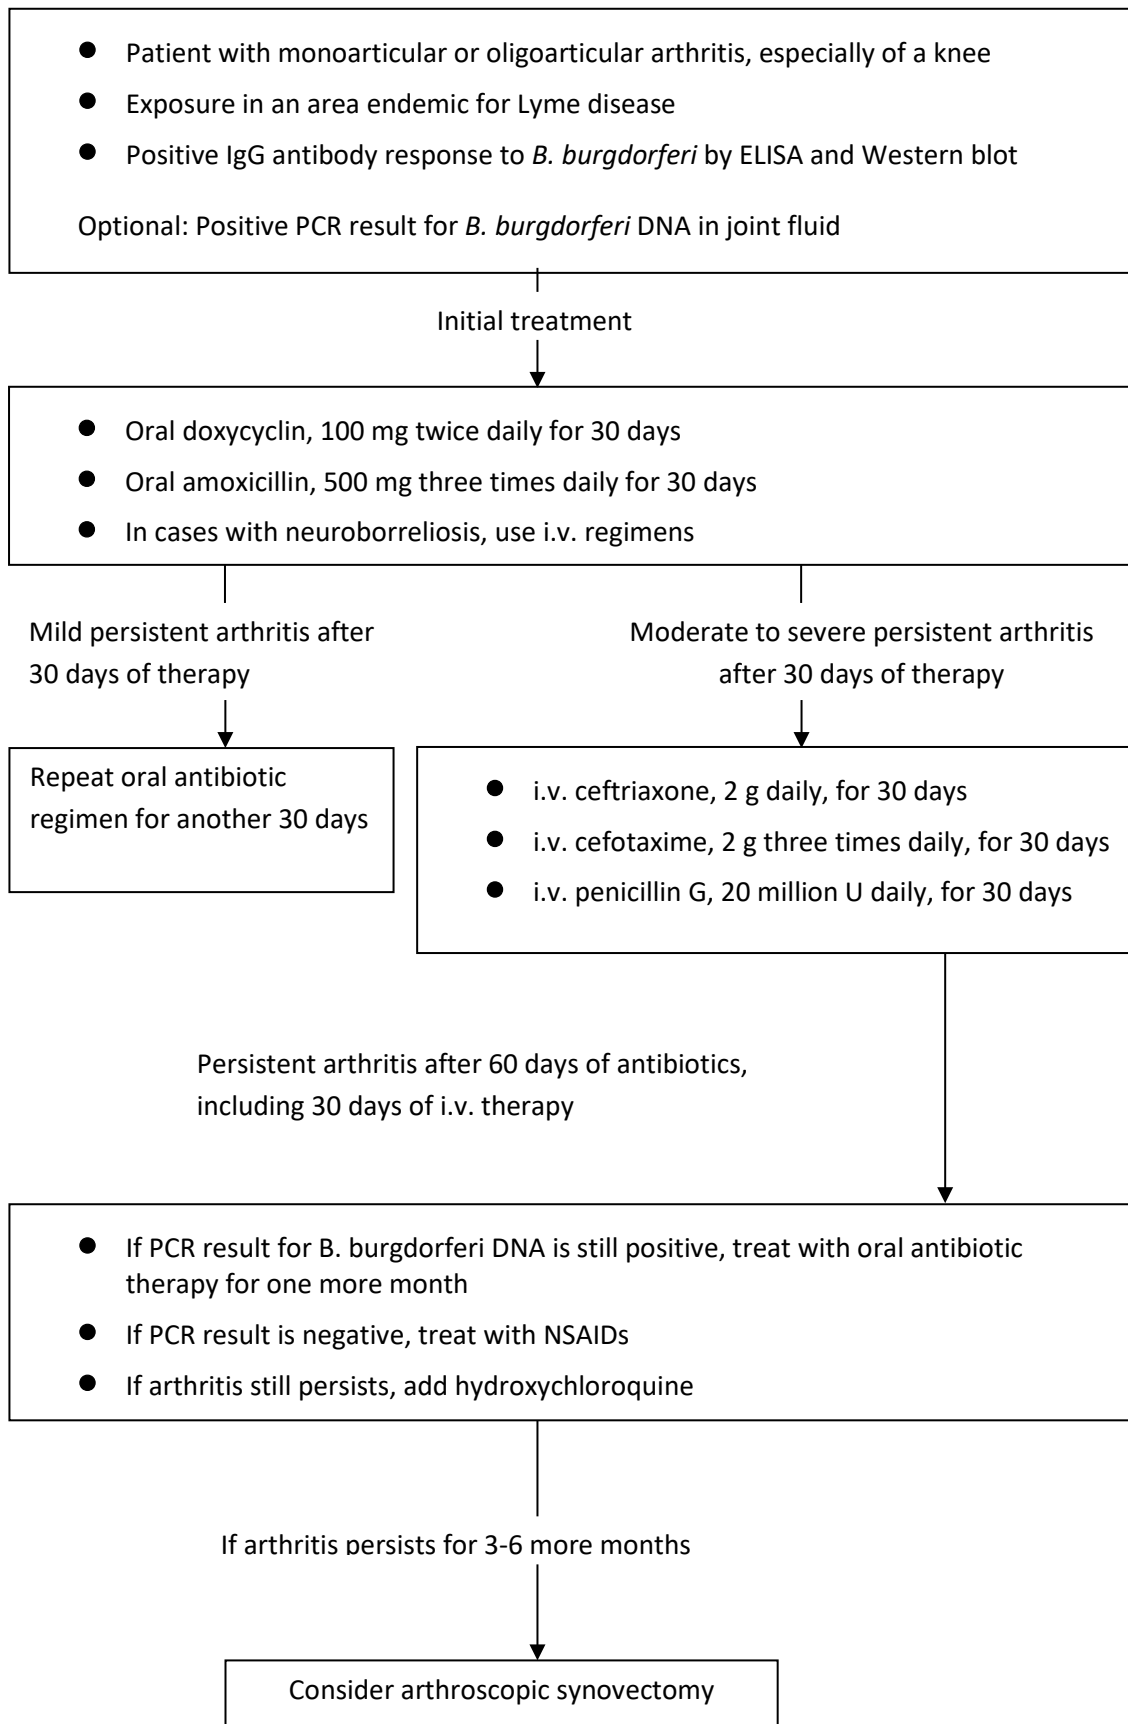

Post-Lyme syndrome

Some patients proceed to have continuous subjective symptoms (such as fatigue, musculoskeletal aches, neurocognitive dysfunction) without objective arthritis. Two controlled studies showed minor or no benefit with antibiotics in such cases. However, the discussion continues with pro (7) and con (8) views for prolonged use of antibiotics for the Post-Lyme syndrome; the situation is complicated by the fact that the symptoms in many patients following their Lyme disease may stem from anxiety or have a psychological basis. The current opinion is that taking into consideration the adverse effects of prolonged antibiotics, such therapy can be hazardous to the patient and is not recommended (3, 9).

1. GOUT

LEARNING OUTCOMES

- Recognise by the clinical presentation those patients with a disease consistent with gout
- Plan the diagnostic investigation, recognising the limitations of a clinical approach
- Be aware that crystal identification in synovial fluid or in an aspirate of a tophus provides an unequivocal aetiological diagnosis
- Be aware that urate crystal deposition—causative of gout—is fully reversible by reducing serum urate levels to normal; after crystals have fully dissolved, features of crystal deposition disappear and gout can be taken as cured as long as uricaemia is maintained at a normal level. Urate crystal dissolution is the main aim in gout treatment
- Manage an acute attack of gout when it does occur
- Recognise the conditions associated with gout, particularly the growing evidence that gout increases the risk of cardiovascular diseases

1.1 Introduction

Gout is an inflammatory disease caused by the deposition of monosodium urate (MSU) crystals in joints and other tissues. The formation of the crystals is the consequence of hyperuricaemia, a condition so called when serum uric acid (SUA) levels are >6.0 mg/dL (360 μ mol/L) (Bardin and Richette, 2014). However, it is important to underline that most patients with hyperuricaemia do not have clinical gout (Richette and Bardin, 2010).

Gout is the most common form of inflammatory arthritis in men and its incidence and prevalence are rising in postmenopausal women. In Western countries, gout affects about 1–2% of adults, with a prevalence increasing with age, being 7% in men over 65 years and 3% in women over 85 years (Roddy and Doherty, 2010). In the UK, the overall prevalence of gout is 2.49% according to a cohort study nested within the Clinical Practice Research Database (CPRD) (Kuo, 2015)

Gout is not a minor disease since it may induce disability and severe nephropathy and increases cardiovascular risk. It is also associated with significant impairment in Health Related Quality of Life (Chandratre et al, 2013).

Deposits of MSU crystals known as tophi may form usually in and around joints but also elsewhere; emerging data suggest that gout is a deposition disease from the first attack or even earlier. Identification of MSU crystals in synovial fluid (SF) obtained during the attacks (McCarty and Hollander, 1961), from previously

inflamed asymptomatic joints of untreated subjects during intercritical periods (Pascual et al, 1999*) or in an aspirate from a tophus is simple and allows immediate unequivocal diagnosis. Ultrasound studies have demonstrated deposition of MSU crystals in patients with asymptomatic hyperuricaemia who have not yet developed clinical manifestations of gout (Pineda et al, 2011; Puig et al, 2008; De Miguel et al, 2012). The disease generally presents with episodes of joint inflammation that in most occasions can be easily treated or avoided. Renal lithiasis and formation of tophi in internal organs and other structures may also occur. Of importance, the crystals slowly dissolve and finally disappear when SUA levels are lowered below a certain threshold (Pascual and Sivera, 2007). Effective and well-tolerated drugs are available for this purpose. Finally, in an important proportion of patients hyperuricaemia is part of the metabolic syndrome and the presence of gout should alert the physician to this problem and its associated morbidities, which may require modification of dietary and lifestyle habits and often drugs. Gout has also been found to be an independent risk factor for atherosclerotic cardiovascular disease (Krishnan et al, 2006). The guidelines on gout diagnosis and management published by the European League Against Rheumatism (EULAR) (Richette and Bardin, 2010*; Bardin and Richette, 2014) and more recently, by the American College of Rheumatology (ACR) (Khanna et al, 2012a*; Khanna et al, 2012b*), outline the current interest in gout.

1.2 Why do crystals form?

Gout is a MSU crystal deposition disease. The formation of the crystals requires (1) raised SUA levels and (2) some local conditions, which are starting to be understood.

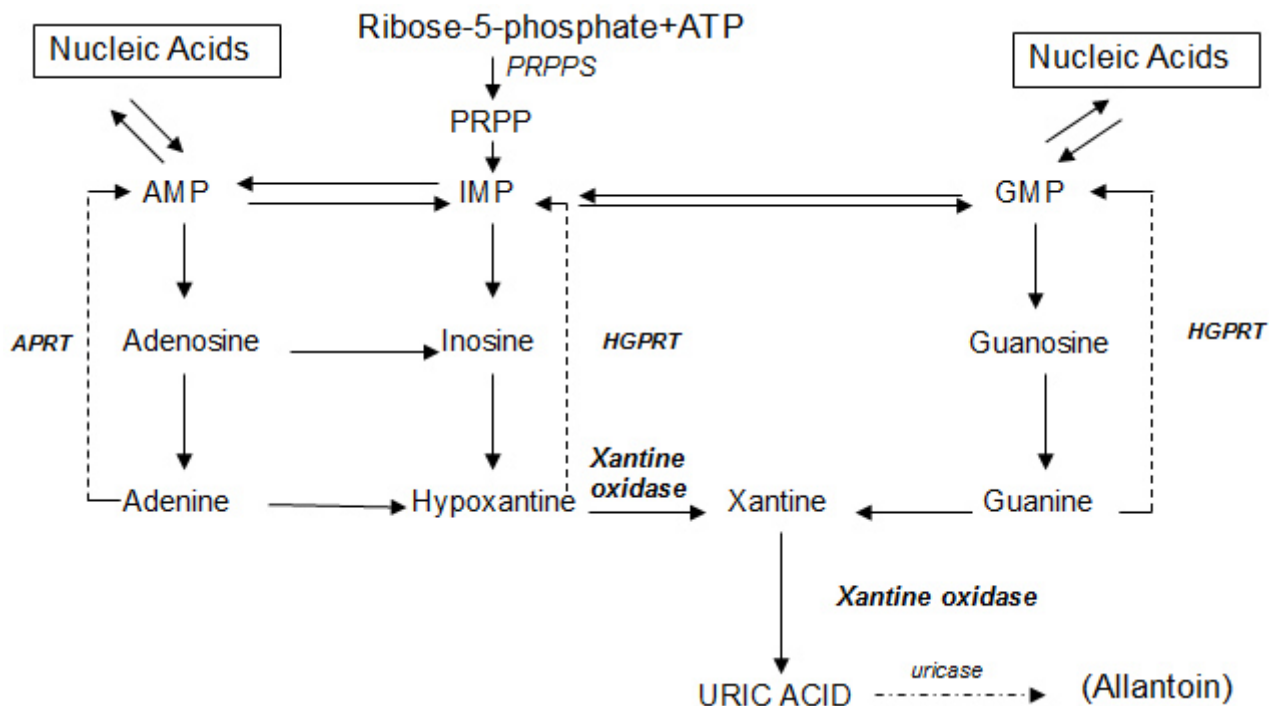

1.2.1 Hyperuricaemia

Uric acid is the final metabolite of purine metabolism in man. Purines are heterocyclic aromatic organic compounds, consisting of a pyrimidine ring fused to an imidazole ring. Uric acid is a weak acid with a pKa of 5.75 (the pH at which uric acid and urate concentrations are equal). At a physiological pH of 7.4 in the extracellular compartment, 98% of uric acid is in the ionised form of urate. Because of the high concentration of sodium in the extracellular compartment, urate is largely present as MSU, with a low solubility limit of about 380 µmol/L (Richette and Bardin, 2010*). So, when urate concentrations exceed this limit, the risk of MSU crystal formation and precipitation increases.

The levels of SUA depend on the balance between purine ingestion, synthesis and degradation. The ingestion of purine and/or urate is very limited, contributing about 10% of the total pool of urate in the body. The main site of the synthesis is the liver. Since purines are difficult to synthesise, during their degradation there are salvage pathways aimed at their reutilisation. The salvage pathways are a major source of nucleotides for synthesis of DNA, RNA and enzyme cofactors. The enzymes most involved in these salvage pathways are adenosine phosphoribosyltransferase and hypoxanthine-guanine phosphoribosyltransferase (HGPRT). At the

distal end of the purine pathway there is the enzyme xanthine oxidase that catalyses the oxidation of hypoxanthine to xanthine, and xanthine to uric acid (figure 1).

Figure 1 Uric acid synthesis.

The starting point of uric acid synthesis is the ribose-5-phosphate, a pentose derived from glycolytic metabolism, converted to phosphoribosyl pyrophosphate (PRPP) and then to phosphoribosilamine, that will be transformed into inosine monophosphate (IMP). From this intermediate compound are derived adenosine monophosphate (AMP) and guanosine monophosphate (GMP), the purinic nucleotides useful for DNA and RNA synthesis, and inosine that will be degraded into hypoxanthine and xanthine and finally, into uric acid by the enzyme xanthine oxidase. Hypoxanthine and guanine may enter in a salvage pathway, using HGPRT, an enzyme that reconverts these purines bases into their respective nucleotides. In a similar salvage pathway, adenine phosphoribosyltransferase (APRT) converts adenosine to AMP.

In humans and other primates, urate oxidase (uricase), a hepatic enzyme, is inactive as a result of a non-sense mutation. So, only animals which possess uricase can transform uric acid in a more soluble and more eliminable molecule: allantoin.

Defects of the enzymes involved in the salvage pathways may cause severe diseases, as in the case of partial or total deficiency of HGPRT, which causes Lesch–Nyhan disease in boys. Another cause of secondary hyperuricaemia is the raised activity of phosphoribosyl pyrophosphate synthetase, in which hyperuricaemia and gout are associated with renal over excretion of uric acid and lithiasis. However, these genetic defects

account for the minority of cases of gout associated with raised production and excretion of uric acid and frequently with urinary lithiasis.

In mammals, the final product of purine degradation is allantoin, which is derived from uric acid by the action of uricase, an enzyme that is lacking in humans and higher primates, owing to mutations affecting uricase (Oda et al, 2002).

SUA levels depend on gender and age. Prepubertal children of either sex have low SUA levels. At puberty SUA levels rise to the levels that will be maintained throughout life owing to a decrease in the renal clearance of urate, at least in women (Roddy and Doherty, 2010); in men these levels rise slightly with age. Oestrogens are uricosuric so that uricaemia will be lower in women up to the menopause or end of hormonal substitution treatment (McCarty and Hollander, 1961; Pascual et al, 1999*). This explains why children do not have gout, with the exception of boys with very unusual enzymatic defects, and of children affected by familial hyperuricaemic nephropathy, an inherited kidney disease with low urinary urate excretion. It also explains why in men the risk of gout starts soon after puberty, while in women gout is exceptional before the menopause. All these aspects were observed by Hippocrates (469–399 BD) who in his aphorisms suggested that women do not have gout while they have their menses, nor do boys before they initiate sexual activity.

Excess uric acid may result from an increase in the amount of purines being degraded, either endogenously from tumours, or haematological conditions like leukaemia or lymphomas, especially when treated, or in psoriasis, or exogenously owing to raised ingestion of purines from food or drinks—in particular, beer or fructose-rich beverages (McCarty and Hollander, 1961; Choi et al, 2004; Choi et al, 2010). For haematological diseases, only patients with chronic conditions develop gout, owing to the time necessary for MSU crystal deposition.

Decreased urate clearance results in raised SUA levels and is the most common cause of gout. In humans, only 5–10% of the filtered urate is finally excreted by the kidneys, the largest part being reabsorbed in the tubules (Hediger et al, 2005). Urate is poorly soluble and has to be transported across cell membranes. Different urate transporters have now been identified: URAT (urate transporter/channel) 1, and GLUT (glucose transporter) 9, two members of the family of organic anion transporters (OAT1 and OAT3) related to tubular secretion of urate and the main protein responsible for tubular reabsorption of urate (Gibson, 2012). The defect in increasing uricuria when uricaemia increases, which characterises most primary hyperuricaemic patients most probably reflects particular polymorphisms of the genes involved in the tubular transport of urate. The calculation of urate clearance is cumbersome and susceptible to errors in a 24 h urine collection. It can be substituted by the calculation of the fractional excretion of urate, which is the relation between urate and creatinine (Cr) clearance and is reported as a percentage. The normal fractional excretion of urate is 7–10%, which represents the percentage of the filtered urate which is finally excreted. The fractional excretion of

urate can be simply calculated on simultaneous spot urine and blood samples (urine uric acid (UA) \times serum Cr/serum UA \times urine Cr) (McCarty and Hollander, 1961; Pascual et al, 1999*). Decreased fractional excretion of urate causes the raised SUA levels which accompany the metabolic syndrome (Pascual and Sivera, 2007)—which is correctable by changing to a low caloric diet (Krishnan et al, 2006)—essential hypertension (Tykarski et al, 1991), decompensated heart failure (Ochiai et al, 2005), saturnine gout—which is correctable by lead chelation (Lin et al, 2001)—and alcohol consumption. Some drugs such as cyclosporine (Lin et al, 1989), low-dose aspirin (Caspi et al, 2000) and diuretics also produce hyperuricaemia by reducing the fractional excretion of urate (Pascual, 1998; Gibson, 2012).

Although the influence of the intestinal excretion of uric acid in SUA levels has not been well evaluated, it seems responsible for about a third of the excretion of uric acid produced daily. Reduced intestinal excretion of urate has been recently shown to be a possible cause of hyperuricaemia (Ichida et al, 2012).

1.2.2 Local conditions for MSU crystal formation

The formation of MSU depends on several factors, including mainly the local concentration of urate. However, its solubility may be influenced by the articular hydration state, temperature, pH, concentrations of cation and the presence of extracellular matrix proteins such as proteoglycans, collagen and chondroitin sulphate.

Variations in these factors may influence the occurrence and the localisation of gout. Although gout may occur in different joints, the disease has a preference for those of the lower extremities such as those in the feet, ankle or knee, where the disease generally starts and the attacks occur more often. The orderly arrangement of MSU crystals on small detached cartilage fragments recovered along SF samples obtained from asymptomatic gouty knees suggests epitaxial formation of the crystals (Pascual et al, 1998). The association between gout and osteoarthritis (OA) in the same joint (Mikkelsen et al, 1965) suggests that cartilage damage related to OA may help to expose collagen fibres which may act as templates for epitaxial formation, prompting MSU crystal nucleation and growth. Sites of deposition of both monosodium urate (MSU) and calcium pyrophosphate crystals have been shown to correlate closely with degenerative lesions in articular cartilage (Muehleman et al, 2008). A clinical diagnosis can be made with reasonable confidence after careful history-taking and examination (tenderness to touch, with subsequent complete resolution affecting the first metatarsophalangeal joint) (Zhang et al, 2006b). Ultrasonography can be used to facilitate arthrocentesis in difficult locations and may reveal or confirm the diagnosis of gout (Punzi and Oliviero 2009). Sonographic studies indicate that MSU crystals form on the surface of the joint cartilage (figure 2), whereas calcium pyrophosphate dihydrate crystals form within its interior (Hall et al, 1967). A decreased permeability of the synovial membrane for urate may facilitate concentration of urate in the joint cavity and enhance crystal nucleation (Choi et al, 2004); also, colder temperature may facilitate formation of tophi in distal joints and in the helix of the ear.

1.3 What triggers the attacks?

Although MSU was identified in gout in the 1700s and shown to be the causative agent in 1899, the mechanisms by which MSU crystals trigger acute inflammation have only recently begun to be understood. After McCarty and Hollander (1961) published their observations that the crystals found in the SF were composed of MSU, these crystals were injected into healthy canine and human joints triggering attacks of gout. From this observation it was implied that the trigger for gouty attacks was the ‘injection’ or shedding of MSU crystals into the joint cavity from surrounding tissues.

Figure 2 Sonography of the first metatarsophalangeal joint: the metatarsal head cartilage is covered by a white line produced by the monosodium urate crystals deposited at its surface. A joint effusion is seen as a dark space. The crystals are bathed by SF explaining their constant presence in SF samples from affected joints, symptomatic or asymptomatic. SF, synovial fluid. (Image provided by Dr Agustín Martínez.)

The inflammation stimulated by MSU crystals is one of the most powerful seen in man. The sequence of events following MSU precipitation concern their physical contact with cells and the interaction with both surface and intracellular receptors that finally leads to the activation of specific inflammatory pathways. Early in the development of the attack, MSU crystals activate monocytes and macrophages with the production of chemotactic substances causing a massive infiltration of neutrophils in the joint fluid and synovial membrane. MSU crystals induce the secretion of a variety of cytokines, prostanoids, chemotactic factors and other proteins, which amplify the inflammatory process through the recruitment of inflammatory cells, the upregulation of adhesion molecules and the stimulation of the acute-phase response (Choi et al, 2005; Lioté and Ea, 2006).

One of the most important advances in the understanding of gout over the past 10 years has been the observation that MSU crystals can activate the NLRP3-inflammasome, a multimolecular intracellular complex

that converts pro-interleukin (IL)-1 and pro-IL-18 into their active forms (Martinon et al, 2006), leading to the concept that gout inflammation involves similar pathways to those of autoinflammatory syndromes (Punzi et al, 2012). The observation that MSU crystals activate the inflammasome places IL-1 β , in particular, at the centre of the gouty inflammatory response (Punzi and So, 2013). Another interesting but unclear aspect is the self-limiting nature of the acute gout attack. It has been suggested that among the various possible causes one of the most relevant might be linked to the differentiation state of the MSU crystal-recruited monocyte population which along their differentiation path into macrophages switch from producing proinflammatory cytokines to producing the anti-inflammatory cytokine transforming growth factor 1 in response to MSU crystal stimulation (Chen et al, 2011; Scanu et al, 2012).

It is important to underline that MSU crystals are regularly found in SF samples from asymptomatic gouty joints of untreated patients, as demonstrated by sonographic studies, showing that the crystals deposit at the surface of the joint cartilage, directly bathed by SF and in an area of contact and friction, explaining their constant presence in joint fluid. In the SF of asymptomatic gouty joints the crystals and white cells interact (as shown by crystal phagocytosis (Pascual and Jovaní, 1995)), resulting in a mild subclinical inflammation (Rouault et al, 1982; Pascual, 1991).

The drop in SUA after the initiation of SUA-lowering drugs is the best characterised trigger of gouty attacks (McCarty and Hollander, 1961); the attacks that frequently accompany severe disease or surgery also can result from the drop in SUA owing to a higher renal clearance which occurs in these circumstances. Also some patients find that overindulgence or ingestion of some foods may trigger attacks. We do not have a conclusive explanation for this.

1.4 Clinical features

The natural history of gout was classically composed of three periods: asymptomatic hyperuricaemia, acute attacks with asymptomatic intervals and chronic gout. However, recent sonographic evidence on the presence of intra-articular microtophi in patients with 'asymptomatic hyperuricaemia', has allowed some authors to suggest the addition of an additional phase 'asymptomatic MSU deposits' after asymptomatic hyperuricaemia and before the acute attack or intermittent flares (Bardin and Richette, 2014).

The classic presentation of acute gout is characterised by a typical rapid development of severe pain, swelling, with overlying erythema and tenderness that reaches its maximum within 6–12 h, often starting at night or in the early morning (Zhang et al, 2006b*).

Most often gout presents as acute monoarthritis and usually it involves a single joint in the lower extremity—in particular, the first metatarsophalangeal joint (podagra), which has been considered as a hallmark of the disease (Bolamaski and Schumacher, 1984). Less often, the disease starts in other joints: tarsal and subtalar

joints, ankle, knee, wrist, metacarpophalangeal or interphalangeal joints of the hand are frequently affected. Inflammation at the Achilles tendon insertion, of the olecranon bursae or patellar tendon is also common (Canoso and Yood, 1979). In about 10% of cases, gout may have an oligoarticular presentation (Lawry et al, 1988). In some cases, the attack of acute gout may involve more joints, in a polyarticular manner, as seen in the elderly, especially women, and in patients who have had a transplant (Meyers and Monteagudo, 1985). In these patients, gout may affect some unusual locations, such as shoulders, hips and small joints of the hands, and may be associated with particular features, such as pitting oedema (puffy hands). Patients with polyarticular gout tend to be older and more often women than those with monoarticular attacks (Meyers and Monteagudo, 1985; De Leonardis et al, 2007). It may occur that patients with gout are seen late after the onset, in a chronic phase, and so it is sometimes difficult to distinguish gout from other chronic arthritis, such as rheumatoid arthritis, psoriatic arthritis or OA (Lally et al, 1989).

Factors that might trigger acute attacks include alcohol intake, heavy meals rich in animal purines, fasting, trauma, infection and surgery (Richette and Bardin, 2010*). Different drugs can also precipitate acute gout by raising or lowering SUA concentrations, such as diuretics and urate-lowering therapy (ULT) shortly after initiation.

Gouty inflammation tends to be very intense and painful. It is characteristic of the disease that the maximal inflammation is reached within a few hours. When peripheral joints or bursa are stricken—such as the first metatarsophalangeal, tarsal, metacarpophalangeal joints, wrist, ankle or the olecranon or Achilles bursa—erythema is common and its intensity appears to be related to the intensity of the inflammation and also to the proximity of the affected structure to the skin (figure 3). Erythematous skin can desquamate after some days. With intense inflammation, regional swelling and erythema are common, such as in the hand with wrist arthritis or in the foot with tarsal arthritis. In deeply seated joints, such as in the knee and frequently ankle, arthritis is often unaccompanied by skin changes and clinically manifests only as pain and swelling. When affecting large joints or if polyarticular it can produce fever and be taken for a septic process. Most often, neglected gout has an episodic nature in which gouty attacks alternate with long intercritical periods, during which the patients are free from symptoms.

Figure 3 Gout attack striking a tarsus which is erythematous and very painful.

As the disease progresses without treatment, gouty attacks tend to be more frequent, affect additional joints and become more polyarticular and persistent, leading to chronic gout. Then, palpable tophi can appear. Gouty inflammation can be less acute and low-grade chronic arthritis also occurs. In older subjects receiving diuretics, gout may result in modest inflammation and simulate or occur at Heberden and Bouchard's nodes (Lally et al, 1989). Gout at prosthetic joints has been reported (Williamson et al, 1994).

Tophi are nodules of a palpable size generally placed near joints and may be the initial clinical feature of gout, but are usually seen in longstanding undiagnosed or improperly treated gout. Tophaceous gout is not a different type of gout; large crystal accumulation just indicates delayed diagnosis or poor treatment. Tophi are often easily seen and can be palpated (figure 4), usually close to joints, and their white content is often seen through the skin (figure 5). When abundant, tophi can result in joint deformation (figure 6). They can also form in the subcutaneous tissue, skin, and their formation along the outer border of the helix is quite characteristic. Also tophi present inside joints can limit movement (Yu et al, 2004). Tophi can be found presenting as masses in many different body locations, resulting in different clinical problems which are finally understood when the mass is sampled and analysed. Aspiration with a needle of a tophus yields a snow white chalky material which is very suggestive of the nature of the nodule, though for an unequivocal diagnosis, the material should be examined by a polarised microscope for definitive identification of the crystals.

Figure 4 Tophus at the olecranon bursa, a common location.

Figure 5 White monosodium urate deposits in a tophus seen through the skin.

Figure 6 Extensive tophaceous gout as seen in a hand. Tophi can be much more extensive than those shown here.

Chronic urate arthropathy is a late feature of neglected gout and is generally associated with palpable tophi. This destructive arthropathy, due to urate infiltration of joints, is responsible for mechanical pain and permanent disability, interspaced with acute or subacute inflammatory episodes. In radiographs, intraosseous tophi and bone erosion by adjacent tophi result in subchondral bone radiolucencies (Dalbeth et al, 2009), often associated with adjacent bone formation, particularly at the erosion edges (bridging osteophytes). Narrowing of cartilage space is characteristically a late event. The association of subchondral bone erosions, osteophytes and long preserved cartilage space is very suggestive of urate arthropathy.

1.5 Diagnosis

Identification of MSU crystals in SF samples drawn from joints undergoing gouty attacks or from tophi allows an unequivocal definitive diagnosis of gout (Zhang et al, 2006b*). It is important to underline that MSU crystals may be found in asymptomatic joints also during the intercritical period, so arthrocentesis should be

performed even in patients referred when the acute attack is resolved (McCarty and Hollander, 1961; Zhang et al, 2006b*).

Thus, joint aspiration is useful and even mandatory in the diagnosis of gout or when there is a suspicion of gout. Owing to the importance of SF analysis for crystal identification, ultrasonography should be used to facilitate arthrocentesis in difficult locations; furthermore, ultrasonography may be useful in revealing or confirming the presence of crystals in SF before arthrocentesis (Punzi and Oliviero, 2009).

MSU crystals dissolve during SUA-lowering therapy and in treated patients finally disappear; the time needed for disappearance relates to the duration of gout (Pascual et al, 1999*).

The technique of crystal detection and identification in SF (described in 'In depth Discussion I') is a simple and reproducible procedure (Pascual et al, 1989); an ordinary microscope allows detection and identification of MSU (figure 7) and calcium pyrophosphate crystals and is good for initiation into the technique of SF analysis for crystals (Lumbreras et al, 2005*) but a compensated polarised microscope remains the standard tool. Recommendations published by EULAR on the diagnosis of gout (Zhang et al, 2006b*) and outcome measures by Outcome Measures in Rheumatology (Schumacher et al, 2005)—and also the 1977 preliminary criteria for classification of the acute arthritis of primary gout (Wallace et al, 1977)—highlight the accuracy of definitive diagnosis by MSU crystal identification. An appropriate microscope is not expensive and must be available in all rheumatology units. It must be kept in mind that when an infectious arthritis occurs at a joint containing MSU or calcium pyrophosphate crystals, the crystals will be present—and identified if searched for—in the SF. So when a joint infection appears possible, the presence of crystals should not deter from culturing the SF.

Figure 7 Monosodium urate crystals in a synovial effusion ×400. Left: simple polarised microscopy; right: compensated polarised microscopy.

1.5.1 Limitations of clinical diagnosis

In general the clinical manifestations of gout are considered to be sufficiently characteristic to allow diagnosis of the disease, and diagnosing gout on clinical grounds remains a widespread practice among rheumatologists and many other physicians. This approach appears to be supported by the use for diagnosis of the 1977 ACR classification criteria of the acute arthritis of primary gout (Wallace et al, 1977) and by tradition; these criteria have been recently validated against MSU crystal identification and have been found to have poor sensitivity and specificity (Malik et al, 2009; Janssens et al, 2010). In very typical presentations (such as recurrent acute podagra in a patient with hyperuricaemia), gout is by far the most likely diagnosis (and alternate diagnoses unlikely), and clinical diagnosis is reasonable (Zhang et al, 2006b). Absence of podagra, oligoarticular or polyarticular gout, gout in women, less acute or less painful attacks, gout in unusual or very unusual locations, unusually placed tophi, gouty attacks with normal SUA levels and simply, acutely inflamed joints of uncertain (and consistent with an infectious) aetiology are not uncommon presentations. Gout in these settings is only diagnosed if MSU crystals are routinely searched for in all SF samples from all unclassified arthritides, as it should be done according to the EULAR recommendations for gout diagnosis (Zhang et al, 2006b*). Many physicians appear to be happy diagnosing gout on clinical grounds when they feel that it is 'typical', but they are likely to consult a rheumatologist to evaluate patients with less evident disease and in whom they feel that the possibilities of misjudgement and error are not acceptable. Rheumatologists should then be prepared to provide a sound definitive diagnosis based on joint aspiration and crystal identification.

When hyperuricaemia accompanies consistent clinical features it makes the diagnosis more likely, but to use hyperuricaemia as an aid to the diagnosis of gout has important limitations. Hyperuricaemia most frequently is asymptomatic and must not be confused with clinical gout, even if US studies have shown that a large proportion of asymptomatic hyperuricaemic subjects have asymptomatic deposits. Only 0.9 people per 1000/year among those whose SUA is between 7 and 7.9 mg/dL (0.42–0.47 mmol/L) will present with gout. The proportion rises to 4.1 per 1000/year when the SUA is between 8 and 8.9 mg/dL (0.48–0.53 mmol/L) and to 49 per 1000/year with SUA concentrations >9 mg/dL (0.54 mmol/L) (Campion et al, 1987). About 7% of adult men have SUA levels above normal. Any clinical feature in these subjects consistent with gout may easily be taken as gout. On the other hand, SUA levels tend to decrease during gouty attacks (Urano et al, 2002; Park et al, 2003); it can be normal at that time and the diagnosis missed. Sensitivity and specificity of SUA levels are too low to be applied as a diagnostic test.

Tophi are formed by MSU crystals and can be the first manifestation of gout, but tophi should be differentiated from other nodular lesions. If a white content is perceived through the skin the chance of a nodule being a tophus is high, but again in unclassified patients confirmation that the presumed tophus contains MSU crystals should be undertaken by needling and polarisation microscopy.

Although gout can result in rather characteristic radiological images, these only form after a sufficiently long period of evolution of gout and so are only present in a small percentage of undiagnosed patients. Additionally, gout can be misdiagnosed if the diagnosis is based on radiological features (Rappaport et al, 1976; Talbott et al, 1978). Radiological changes have never been critically evaluated for their diagnostic value in gout.

MSU crystal deposits can be detected by sonography, which shows crystals deposited along the surface of the joint cartilage, and also in synovial tissue and tendons. MSU crystals floating in SF are shown by sonography as small echoic aggregates (Grassi et al, 2006*). Subcutaneous or periarticular tophi are also visualised well (Wright et al, 2007). The possibility of using sonography to diagnose gout has received consideration (Thiele and Schlesinger, 2007). Although this is an appealing possibility, studies to determine sensitivity—mostly at the time of the first gouty attack when MSU deposits are likely to be small—and specificity of MSU crystal identification are required before adopting this technique for diagnosis (Chowalloor and Keen, 2013).

1.6 Hyperuricaemia, gout and comorbidities

Gout may be classified as primary or secondary, depending on the presence or absence of an identified cause of hyperuricaemia (Bardin and Richette, 2014). Frequently primary gout may be accompanied or associated with other conditions, including obesity, alcohol consumption, hypertension, type 2 diabetes mellitus, obstructive sleep apnoea and hypertriglyceridaemia (Roddy and Choi, 2014; Zhang et al, 2015). Secondary gout may be the consequence of specific drugs, mainly diuretics, and drugs used in organ transplantation, in particular cyclosporine and tacrolimus; and to a lesser extent low-dose aspirin.

Nephropathy is often found in association with gout. The presence of kidney stones is most common, occurring in 10–40% of patients, with a risk twofold higher than for subjects without gout. Furthermore, an association between hyperuricaemia and renal dysfunction has been observed, independently of urate crystal formation (Bardin and Richette, 2014).

Patients with hyperuricaemia and/or gout should be carefully assessed for the presence of metabolic syndrome, since its prevalence may be very high, up to 60–70%. The presence of metabolic syndrome may explain the presence of an increased cardiovascular risk in patients with hyperuricaemia and mainly, with gout (Pascual and Sivera, 2007). Moreover, studies have shown that gout is an independent risk factor for cardiovascular risk and also for increased all-cause mortality (Krishnan et al, 2006).

1.7 Treatment

1.7.1 Aims of treatment

The management of gout may include different approaches depending on the type of disease presentation and individual patient characteristics. However, the main aims of treatment are the treatment of acute attacks and the cure and/or the prevention of chronic disease, by achieving dissolution of the pathogenic MSU crystals.

So, when planning to treat a patient with gout, several aims have to be independently considered:

1. Gout is a reversible MSU crystal deposition disease; the reduction of SUA to normal levels results in the dissolution of the crystals. The final aim of the treatment of gout is to eliminate the urate crystals; without crystals the possibility of joint inflammation ceases and the disease can be taken as 'cured' (Richette et al, 2016) (although SUA needs to be maintained in the normal range indefinitely to avoid formation of new crystals and the return of gout).
2. Avoidance of inflammatory episodes in joints still containing MSU crystals by appropriate prophylactic treatment.
3. Treatment of the crystal-associated inflammation, which occurs at the initial stage of gout or may recur after the start of urate-lowering treatment, often triggered by dose increases.
4. Finally, causes of gout should be looked for, and other conditions associated with gout, of which the most common is metabolic syndrome, should be recognised and treated.

1.7.2 Acute attack

Owing to the intensity of the inflammation during the acute attack, acute treatment is directed towards reducing inflammation rather than eliminating crystals. Standard treatment includes non-pharmacological treatment, such as rest and application of ice to the affected joints and mainly, pharmacological modalities. According to the pathogenesis of the attack, drugs should be able to combat inflammation and subsequently induce a rapid relief of the symptoms. The most appropriate drugs for this are anti-inflammatory substances, which include traditional drugs such as colchicine, non-steroidal anti-inflammatory drugs (NSAIDs) and steroids, and innovative drugs, such as the biological drugs acting as IL-1 inhibitors, in patients with inadequate response or contraindication/intolerance to standard drugs. Overall, all anti-inflammatory drugs work much better when given early after the onset of gouty flares.

As already noted by Hippocrates, gouty attacks subside spontaneously after a short period; drugs with anti-inflammatory properties hasten the process and most often result in a rapid relief of the symptoms. It is accepted that treatment early after the start of an attack results in faster resolution.

All drugs indicated for an acute attack may be used alone or in combination with each other. The treatment can be maintained after subsidence to avoid rebounds, generally at lower, prophylaxis doses of a single drug.

1.7.2.1 Colchicine

EULAR and ACR guidelines (Richette et al, 2016; Khanna et al, 2012b*) recommend low doses of colchicine for the treatment of an acute attack, given early after the attack onset, at a loading dose of 1 mg followed 1 h later by 0.5 mg on day 1 (Richette et al, 2016; Khanna et al, 2012b*).

Colchicine is an alkaloid derived from a plant, the *Colchicum autumnale*, which has a long tradition in the treatment of gout. However, there are some concerns about its frequent side effects, especially abdominal complaints, diarrhoea and vomiting, which, however, are generally quickly reversible. In a placebo-controlled trial of high-dose colchicine (1 mg immediately followed by 0.5mg every 2 hours, although colchicine was effective, every patient in the colchicine group experienced diarrhoea and/or vomiting (Ahern et al, 1987). Hence, such high-dose regimes are best avoided.”

A recent trial has shown that, when given in the first 12 h, a lower-dose regimen (two 0.6 mg tablets followed in 1 h by one 0.6 mg tablet) was equally effective for acute gout but with fewer side effects than a higher dose (two 0.6 mg followed by 6-hourly doses of 0.6 mg) (Terkeltaub et al, 2010*). However, other low-dose regimes such as 0.5mg two to four times daily are not uncommon in clinical practice yet have not been evaluated in randomised trials (Roddy and Doherty, 2010 ; British National Formulary). Continuation of a lower dose of colchicine (0.5 mg twice a day) is usually needed for 1–2 weeks to treat the attack, and for several months if a urate-lowering drug is introduced to prevent ultra-low-dose (ULT)-induced flares. Colchicine can be used in combination with other anti-inflammatory drugs in acute gouty attacks, possibly in doses lower than when used alone.

A true severe toxicity, with myelotoxicity and myotoxicity, is uncommon and usually related to very high doses and/or to prolonged use, most often in older patients with renal, hepatic or other comorbidities. Colchicine dose reduction or non-prescription is recommended in these patients and in those taking lipid-lowering drugs and drug inhibitors of cytochrome P450 3A4 and P-glycoprotein, such as clarithromycin, erythromycin, cyclosporine and disulfiram.

1.7.2.2 NSAIDs

All NSAIDs given to treat acute attacks of gout have shown efficacy. NSAIDs are considered a convenient and well-accepted therapeutic option (Richette et al, 2016; Khanna et al, 2012b*); the choice of a specific NSAID is largely a matter of personal preference (Bardin and Richette, 2014). It appears advantageous to use full doses of the selected drug unless contraindications are present. Among NSAIDs, indomethacin has traditionally been considered to be a particularly effective agent, however, there is no evidence to support its effectiveness over

any other NSAID and it is best avoided in view of frequent toxicity (Roddy and Mallen, 2013). Cyclo-oxygenase 2 (Cox-2) inhibitors are an option in patients with gastrointestinal contraindications or intolerance to NSAIDs. Major limitations of the conventional NSAIDs are the well-known side effects of the group—gastrointestinal, cardiovascular and renal—and the possibility of interactions with other drugs taken by the patient. Gouty attacks often strike aged patients with comorbidities, in whom NSAIDs can be hazardous, especially in elderly patients taking oral anticoagulants. Although distressing and painful, gouty attacks only exceptionally constitute a major health problem so effective therapeutic alternatives to NSAIDs should be seriously considered.

1.7.2.3 Glucocorticoids

A short course of systemic glucocorticoids (such as 30–35 mg of prednisone for 3–5 days with a rapid tapering off) (Groff et al, 1990; Janssens et al, 2008) has been found effective. Recent ACR guidelines recommend starting treatment with oral prednisone 0.5 mg/kg per day with a duration of 5–10 days or 2–5 days at full doses, then tapering for 7–10 days and then stopping (Khanna et al, 2012b*). However, short courses of glucocorticoids can be followed by a rebound attack of gout. To avoid this, co-administration of prophylactic doses of colchicine (0.5–1.5 mg/day) from the start of the glucocorticoid treatment may help.

Intra-articular glucocorticoids, even in small doses (Fernández et al, 1997), are effective especially when large joints are affected and may minimise the systemic effects of these drugs and are safe if joint infection has been excluded. As suggested above, intra-articular treatment could be used in combination with oral glucocorticoid, colchicine or an NSAID (Khanna et al, 2012b*).

A few studies support the rapid effectiveness of parenteral adrenocorticotrophic hormone, which is considered by ACR recommendations (Khanna et al, 2012b*) for patients unable to take oral anti-inflammatory drugs (Fernández et al, 1997).

1.7.2.4 Off-label therapy: the interleukin-1 blockade

Refractory gouty attacks have not been critically defined and the approach to the treatment of 'refractory' gouty inflammation has only received anecdotal attention. However, this might, in some cases, be a serious problem. Owing to the role of IL-1 β in gouty inflammation, some authors have proposed the use, in refractory cases, of agents which can block this cytokine. At present three such agents are available. Two of these, canakinumab and rilonacept (also known as IL-Trap) are Food and Drug Administration (FDA) and EMA approved for cryopyrin-associated periodic fever syndromes. Anakinra is FDA and European Medicines Agency (EMA) approved for rheumatoid arthritis. Each of these agents has recently been investigated in refractory gout, with promising results in both acute attack and prophylaxis. The most important difference in clinical use among these three agents is their half-life, the longest being canakinumab (21–28 days), followed by

rilonacept (34–57 h) and anakinra, which is the shortest-acting IL-1 β antagonist, with a half-life of 4–6 h. Anakinra, a recombinant IL-1 receptor antagonist was the first of these agents to demonstrate efficacy in an open-label trial in 10 patients with acute gout (So et al, 2007). Another study provided a positive signal to suggest that rilonacept may offer a well-tolerated approach for reducing pain in patients with chronic active difficult gouty arthritis not adequately managed with other treatments (Terkeltaub et al, 2009). Two recent randomised, multicentre, double-blind trials showed that treatment with canakinumab provided significant pain and inflammation relief and reduced the risk of new flares in patients with acute gouty arthritis (Schlesinger et al, 2012), leading to recent EMA approval.

These preliminary results support the hypothesis that IL-1 blockade may be a useful and selective treatment strategy for the growing population of patients with gout, including chronic, refractory gouty arthritis, who cannot tolerate standard treatments such as NSAIDs, colchicine or glucocorticoids. Obviously, as for rheumatoid arthritis, current infection is a contraindication to the use of IL-1 blockers.

1.7.3 Urate-lowering therapy

Because hyperuricaemia is the absolute prerequisite of gout, the primary objective of SUA-lowering therapy is to maintain urate concentration below the saturation point for MSU. This treatment dissolves crystal deposits and cures gout while it is maintained. EULAR and ACR guidelines recommend that plasma or serum urate should be maintained at a concentration of <6 mg/dL (360 μ mol/L) (Richette et al, 2016; Khanna et al, 2012a*). However, this target serum level can be lowered to <5 mg/dL (300 μ mol/L) in the presence of severe tophaceous gout (Khanna et al, 2012a*). Lower SUA levels result in faster reduction of the size of tophi (Perez-Ruiz et al, 2002b) and the same presumably occurs with crystals deposited in joints. However, whilst it appears rationale to recommend reducing SUA levels as much as reasonably possible, particularly in patients with long-standing tophaceous or polyarticular gout, a cautionary note has been introduced by the observation that hyperuricaemia may be protective against the incidence and progression of neurodegenerative disease (Acherio et al, 2009 ; Eusar et al, 2009; Auinger et al, 2010 ; Paganoni et al, 2012 ; Jain et al, 2011). The implications of this for lowering SUA in the context of treating gout are unknown, however, the revised EULAR management guideline advises against maintaining very low SUA levels in the long-term (Richette et al, 2016). In patients with gout of longer duration, the time of disappearance of MSU crystals from signal joints induced by normalisation of SUA levels has been shown to be longer (Perez-Ruiz and Liote, 2007*).

There is no general agreement about the right time for starting SUA-lowering therapy (ULT). Suggestions vary from very early initiation after the initial attacks to not starting this treatment unless the patient has several attacks per year, or develops chronic arthritis or tophi, radiological lesions or uric acid renal calculi. However, early treatment may be advantageous because the aim of SUA-lowering therapy is to dissolve all MSU crystals and this takes less time when gout is more recent. Furthermore, gout has been identified as an independent

risk factor for atherosclerotic cardiovascular disease, the level of this association rising with the severity of gout, also in women (De Vera et al, 2010). Crystal disappearance might lead to the diminution or disappearance of this risk factor. Finally, SUA levels should be maintained within normal values after elimination of the MSU crystals from the joints, otherwise crystals will form again and with them gouty inflammation returns (Bull and Scott, 1989; van Lieshout-Zuidema and Breedveld, 1993). Therefore after the crystals have dissolved, unless dietary and lifestyle modifications are sufficient to reduce SUA to normal levels, SUA-lowering therapy should continue. The best method of ascertaining that MSU crystals have disappeared from the joints remains undetermined, although sonography seems to be useful (Chowalloor and Keen, 2013). In any case, if SUA levels are to be kept within normal values indefinitely, the need to ascertain the disappearance of crystals has limited clinical value.

For all SUA-lowering drugs it is an often accepted rule that they should not be started until the gouty attack has fully resolved; furthermore, it must be kept in mind that the initiation or increase in dosage of SUA-lowering therapy in patients with gout frequently results in a gouty attack if prophylactic colchicine is not co-administered—for example, at 0.5–1 mg/day.

The ULT could be started during an acute attack, provided that the anti-inflammatory therapy has been instituted and is effective. The dose of drug used in ULT should initially be low and progressively increased until the achievement of the target serum urate level. It is important to monitor SUA levels during ULT titration, approximately every 2–4 weeks.

Three classes of drugs are approved for ULT: xanthine oxidase inhibitors, uricosuric agents and uricase agents. Xanthine oxidase inhibitors block the synthesis of uric acid.

1.7.3.1 Allopurinol

Since its introduction, allopurinol has become the mainstay urate-lowering drug and so it is used as first-line ULT. It has been used extensively, is inexpensive and for most patients with gout it is a safe and effective option. Allopurinol is a purine analogue that competitively inhibits xanthine oxidase, the enzyme responsible for the degradation of hypoxanthine and xanthine to uric acid, reducing the total amount of uric acid formed. The starting dose of allopurinol should be no greater than 100 mg/day, consistent with EULAR and ACR guidelines (Richette et al, 2016; Khanna et al, 2012a*), and should be increased progressively until a target uric acid concentration or maximum dose is achieved. This low dosage could reduce the early gout flares after ULT initiation, and the risk of a rare but severe hypersensitivity reaction to allopurinol. Cutaneous intolerance to allopurinol occurs early (in the first 3 months) of allopurinol introduction or dose increase and should prohibit any further allopurinol use. In patients with healthy renal function, daily doses can be raised to 300–600 mg, and even to 900 mg/day in rare cases.

Data drawn from different series show that in a substantial percentage of allopurinol-treated patients the SUA levels attained are insufficient for crystal dissolution, but this probably relates to the widespread use of 300 mg/day as a fixed dose.

The allopurinol dose needs correction according to renal function, since levels of oxypurinol, the main metabolite of allopurinol, are related to the glomerular filtration rate (Emmerson et al, 1987). Published standards for quality care recommend dose reductions of allopurinol and avoidance of NSAIDs in patients with Cr clearance <50 mL/min (Mikuls et al, 2004). Allopurinol dose adjustment to renal function is also recommended by the EULAR and ACR guidelines (Richette et al, 2016; Khanna et al, 2012a*), to avoid toxicity. For many years, dose adjustment has followed the recommendations by Hande et al based on the maximum permitted allopurinol dose per level of renal impairment (Hande et al, 1984). More recently, a regime based on the starting dose of allopurinol has been shown to reduce the incidence of allopurinol hypersensitivity syndrome (Stamp et al, 2012). Of importance, reduction of SUA has been found to improve renal function in both non-gouty (Siu et al, 2006) and gouty patients with renal insufficiency (Perez-Ruiz et al, 2000).

Azathioprine is metabolised also by xanthine oxidase; allopurinol interferes in its metabolism and their co-administration results in higher levels of azathioprine, risking marrow suppression. Coadministration is therefore not recommended, although a regime for adjustment of the dose of azathioprine exists (Witte, Allen, 2008). In kidney transplant recipients with gouty arthritis, mycophenolate mofetil may be substituted for azathioprine (Jacobs et al, 1997), allowing a safer use of xanthine oxidase inhibitors.

The allopurinol hypersensitivity syndrome remains a serious and potentially lethal hazard, which can develop within the 3 first months of allopurinol introduction or titration (Jacobs et al, 1997). Severe allopurinol-induced toxic effects arise in <1% of patients but can be life threatening, with a mortality rate of about 20% (Gutierrez-Macias et al, 2005; Bardin and Richette, 2014).

For mild cases of the allopurinol hypersensitivity syndrome desensitisation may be an option (Fam et al, 1992), but it is hazardous in more severe cases. An association of severe hypersensitivity reaction with human leucocyte antigen (HLA-B*5801) has been observed in Chinese and Korean patients, so HLA testing should be considered in these populations before starting allopurinol treatment (Khanna et al, 2012a*).

The general approach to both allopurinol hypersensitivity and refractoriness, generally, is to apply alternative drugs.

1.7.3.2 Non-purine inhibitor of xanthine oxidase: febuxostat

Febuxostat is a non-purine selective inhibitor of xanthine oxidase, approved for the management of gout in the USA and in the European Union. The doses of 80 mg/day and 120 mg/day, which have been approved in Europe, have shown better efficacy than 300 mg/day allopurinol in controlled studies (Becker et al, 2005a;

Becker et al, 2005b). Since metabolism occurs in the liver via glucuronide formation and oxidation, with about 50% of the drug excreted in stool and 50% in the urine, febuxostat dose adjustments are not needed in patients with mild to moderate renal failure (Mayer et al, 2005). Febuxostat provides an advantageous alternative for patients in whom allopurinol cannot be used at appropriate doses because of renal insufficiency or intolerance. Febuxostat is not recommended for patients with severe heart disease. With regard to severe cutaneous reactions, in one study, 12 of 13 patients with gout and previously documented severe allopurinol adverse events tolerated subsequent febuxostat treatment safely. However, the development in one case of a hypersensitivity-type cutaneous vasculitis, probably but not definitively febuxostat-related, mandates caution, careful dose escalation and close monitoring when febuxostat is considered for allopurinol-intolerant patients (Chohan, 2011).

1.7.3.3 Uricosuric drugs

Uricosuric drugs work by raising the renal clearance of urate. The most used are probenecid, sulfinpyrazone and benzbromarone. They are valid options as second-line therapy especially if use of allopurinol is problematic. Treatment with uricosuric drugs makes sense since the majority of patients with gout have impaired renal excretion of uric acid (Perez-Ruiz et al, 2002a; Pascual and Perdiguero, 2006) which can be normalised by these drugs. Since uricosuric drugs are associated with a high risk of urolithiasis, they are contraindicated in patients with a history of urolithiasis. Furthermore, fluid intake should be increased and urine pH maintained above 6 to prevent development of uric acid stones (Richette and Bardin, 2010*).

Benzbromarone remains available in some European countries, although with restricted use, but not in the USA. It is mainly indicated in the treatment of patients refractory or intolerant to allopurinol (Kumar et al, 2005). It can be used in patients with moderate renal insufficiency (Pérez-Ruiz et al, 1999), and has been a successful option for transplanted patients with gout (Zürcher et al, 1994; Marcén et al, 1995). In Europe the drug was discontinued because of rare cases of fatal liver toxicity, but a review has shown that deaths are no more frequent with benzbromarone than with allopurinol or colchicine (Jansen et al, 2004). A typical starting dose of benzbromarone would be 50 mg daily, to be increased in steps of 50 mg to the maintenance dose (often 100–200 mg day) required to reach the SUA target, whilst carefully monitoring liver function (Lee et al, 2008).

The recent ACR recommendations suggest that probenecid should be preferred as first choice among uricosuric drugs available in the USA (Khanna et al, 2012a*), and underline that uricosuric drugs have to be used cautiously, at the same time as alkalinising the urine and raising the ingestion of fluids, but only if there is no other rational option available. For difficult cases of patients refractory to allopurinol the combined use of allopurinol, which decreases the total amount of urate formed, and a uricosuric drug, which by raising the renal urate clearance decreases the SUA levels further, often works well and is worth trying.

1.7.3.4 Uricase

In all mammals, except man and higher primates, who lost uricase through mutations (Oda et al, 2002), uricase degrades uric acid to allantoin which is soluble and can be easily disposed. In humans uricase is a very effective means of preventing and treating tumour lysis syndrome and SUA levels as low as 0.78 ± 0.4 mg/dL (0.05 mmol/L) after 4 h of administration can be achieved (Goldman et al, 2001). Rasburicase, a recombinant uricase, has been now successfully used in unusually severe cases of gout (Vogt, 2005; Richette and Bardin, 2006). At present, a pegylated (to increase the half-life of the drug) uricase has been approved by the FDA and EMA for the treatment of severe refractory gout (Becker et al, 2013). These drugs appear to be able to deplete urate deposits faster than other available drugs and could be used if considered especially convenient. Their proper place in the management of gout will become established as we gain experience with them.

1.7.3.5 Other drugs

Losartan, calcium pump inhibitors, statins and clofibrate are uricosuric and have a SUA level reducing effect. The effect of losartan has been found sometimes to be transient, but fenofibrate has a long-lasting effect. They can be useful adjuvants in the management of patients with gout, who can also benefit from their effect in reducing blood pressure and lowering lipids.

1.7.4 Prophylaxis of ULT-induced gouty attacks

Urate lowering frequently induces mobilisation of persisting urate crystals, resulting in the occurrence of acute flares when ULT are started. This should be explained to the patient and prevented as such flares can make the patient stop taking the ULT. The daily administration of 0.5–1.5 mg colchicine avoids in most cases such ULT-induced attacks of inflammation (Yu, 1992). Prophylaxis is recommended during the first 6 months (Borstad et al, 2004). In any case, after initiation of SUA-lowering therapy, gouty attacks may still occur until the joint is free of crystals, and for complete avoidance of attacks, colchicine therapy should be maintained until their complete dissolution. The initiation and increase in dose of SUA-lowering therapy often results in an attack of gout if prophylaxis is not co-administered. It has been noted that after prolonged successful SUA-lowering therapy gouty attacks became less frequent (Sarawate et al, 2006); this may be related to the decrease in the concentration of MSU crystals in joints as a result of the SUA-lowering therapy, already apparent at 3 months after its initiation (Roddy and Doherty, 2010). For the few patients who are intolerant even to small daily doses of colchicine, an every other day schedule can be tried. A small dose of a NSAID, such as naproxen 250mg daily, or oral prednisolone 5-7.5mg daily, can be an appropriate alternative if colchicine cannot be tolerated. A minority of patients usually with longstanding poorly treated gout have attacks when starting SUA-lowering drugs even if given prophylaxis with a proper dose of colchicine. For these patients it is worth giving, in addition to an incremental progressive increase in SUA-lowering treatment (as allopurinol given in 100 mg increments), a more complete prophylaxis including colchicine and a small dose of an NSAID. Occasionally,

patients need the addition of prednisone 5–7.5 mg/day to colchicine for 1–3 months to allow an uneventful start of SUA-lowering treatment. For patients with especially difficult prophylaxis, IL-1 blocking by canakinumab or anakinra may be an alternative to consider. In the long term the best prophylaxis is to implement proper SUA-lowering treatment and dissolve all MSU crystals, since in their absence gout does not occur.

1.7.5 Dietary and lifestyle factors, medication

The popular association of gout and other diseases with the overindulgence in alcohol and food associated with wealth predates modern medicine. Hyperuricaemia and gout are now considered as elements of the metabolic syndrome, where hyperuricaemia results mainly as a consequence of a decreased renal clearance of urate. In these subjects a hypocaloric diet decreases SUA levels by increasing urate clearance (Tirahones et al, 1997) and, if the diet is also low in fat, it is also beneficial for the often coexisting obesity, hypertension and hyperlipidaemia (Miller et al, 2006). The increasing prevalence of gout, in general, has been related to dietary changes. Gout associated with the metabolic syndrome shares the comorbidities of the group, mostly related to atherosclerosis. Gout has now been independently associated with myocardial infarction, the level of this association rising with the severity of gout (Krishnan et al, 2006). No doubt the benefits of appropriate lifestyle changes go far beyond their effect on gout (Choi and Curhan, 2005). The attention to comorbid conditions is considered as a key issue in recently published recommendations on gout management (Richette et al, 2016; Khanna et al, 2012a*). The relation of lifestyle changes and diet with gout has been extensively reviewed (Choi and Curhan, 2005; Fam, 2005; Lee et al, 2006; Saag and Choi, 2006; Choi et al, 2008). In addition to reduced intake of food rich in purine (such as anchovies, herring and animal organs) and alcohol, sugar-sweetened soft drink consumption should also be kept to a minimum, as the latter also is associated with hyperuricaemia, in contrast to diet soft drinks (Choi and Curhan, 2008; Choi et al, 2008).

2. Calcium pyrophosphate crystal deposition disease

LEARNING OUTCOMES

- ➔ To outline the terminology recommended by the EULAR
- ➔ To describe and explain the epidemiology and the various aetiologies of the disease
- ➔ To describe and explain the pathophysiology of calcium pyrophosphate (CPP) crystal deposition and of CPP crystal-induced inflammation
- ➔ To describe the multiple clinical presentations of CPP
- ➔ To outline the links between osteoarthritis and CPP crystal deposition
- ➔ To diagnose CPP crystal deposition disease, according to the EULAR recommendations
- ➔ To manage CPP crystal deposition disease, according to the EULAR recommendations

2.1 Introduction

Three types of calcium-containing crystals can be observed in and/or around joints (table 1). Calcium oxalate crystal deposits are very rare and occur almost exclusively in patients with primary or secondary oxalosis who are undergoing dialysis. Basic calcium phosphate deposition is the main cause of calcific tendinitis/bursitis. Calcium pyrophosphate (CPP) dihydrate crystals are commonly found in the joints of the elderly and can occasionally be observed in periarticular tissue. These three types of calcium-containing crystals are associated with a variety of clinical features but are frequently asymptomatic. This paper focuses on CPP dihydrate crystal deposition disease.

Table 1 Intra-articular and periarticular calcium crystal deposits

	Intra-articular	Periarticular
CPPD	+++	+
BCP	+	+++
Ca Oxalate	++	++

BCP, basic calcium phosphate; CPPD, calcium pyrophosphate deposition.

2.2 Terminology

To simplify a terminology which has been variable and confusing, EULAR has recently issued recommendations (Zhang et al, 2010), according to which CPP dihydrate crystal is abbreviated as CPP crystal. CPP deposition (CPPD) stands as the umbrella term for the conditions related to this disorder, including acute CPP crystal

arthritis (formerly frequently called ‘pseudo-gout’), osteoarthritis (OA) with CPPD (formerly ‘pseudo-OA’) and chronic CPP crystal inflammatory arthritis (formerly ‘pseudo-rheumatoid arthritis (RA)’). Chondrocalcinosis (CC) is cartilage calcification, most commonly due to CPPD and detected by imaging or histological examination.

2.3 Epidemiology

CPPD is mainly a disease of the elderly (Richette et al, 2009). Prevalence of radiological CC in Caucasians is very low before 55–60 years of age but subsequently increases: 15% between 65 and 74 years; 36% between 75 and 84 years and 44% in those aged ≥ 85 years according to one study (Wilkins et al, 1983). One community study in the UK confirmed an increased prevalence of CC with age: from 3.7% for those aged 55–59 years to 17.5% for those aged 80–84 years (Neame et al, 2003). Prevalence may be lower in Chinese people (Zhang et al, 2006). Most patients with early CPPD have familial or secondary disease.

2.4 Classification

CPPD can be a familial disease, which is most frequently recognised as an early onset severe disease but has also been identified in the elderly with the usual clinical presentations (Fernandez Dapica and Gomez-Reino, 1986; Reginato et al, 1995). CPPD can also be secondary to a number of metabolic diseases (table 2) (Jones et al, 1992; Richette, et al, 2009), including primary hyperparathyroidism (Rynes and Merzig, 1978), haemochromatosis (Pawlotsky et al, 1999) and hypomagnesaemia (Richette et al, 2007), some of which can also be familial. CC can also develop in operated or traumatised joints (Doherty et al, 1982; De Lange and Keats, 1985). CC has also been reported to associate with low cortical bone mineral density (Abhishek et al, 2014). Most patients with CPPD have no familial or predisposing disease. This idiopathic or sporadic CPPD particularly involves the elderly.

Table 2 Conditions associated with calcium pyrophosphate deposition

Definite associations	Possible associations
Hypophosphatasia	Gout
Primary hyperparathyroidism	Ochronosis
Familial hypercalciuric hypercalcaemia	Wilson’s disease
Haemochromatosis	Hypophosphataemic rickets
Hypomagnesaemia	Brachydactyly and epiphyseal dysplasias
	Acromegaly

2.5 Pathophysiology

CPP deposits occur mainly in the mid-zone of articular cartilage and in fibrocartilage of joints (figure 1) and are believed to be due to a locally excessive $[Ca \times PP]$ product. Early studies have shown that pyrophosphate (PPi) concentrations are normal in the serum (except for patients with hypophosphatasia) but elevated in the synovial fluid (SF) of patients with CPPD or in patients affected by a metabolic disease which predisposes to CPPD (Doherty et al, 1991). PPi is abundantly produced by cells, following the metabolism of ATP during synthetic processes, but intracellular PPi cannot passively cross intact cell membranes. Two mechanisms are known to release PPi outside the cells (figure 2). The ecto-enzyme plasma cell glycoprotein 1 (PC1) hydrolyses extracellular nucleotide triphosphate, resulting in PPi release outside the cell. A PPi transporter, ankylosis human (ANKH), allows intracellular PPi to be excreted across the cell membrane (Ho et al, 2000; Netter et al, 2004). A second ectoenzyme, alkaline phosphatase metabolises extracellular PPi to orthophosphate, explaining the increased PPi concentration and CPPD incidence in hypophosphatasia (Chuck et al, 1989). Activating mutations of the ANKH gene have been identified in some, but not all, patients with familial CC (Pendleton et al, 2002). ANKH activity can be increased by cytokines such as transforming growth factor β , and this, together with some polymorphisms of the gene (Zhang et al, 2005), might be an explanation for idiopathic (sporadic) CC. Magnesium is a coenzyme to alkaline phosphatase and increases CPP solubility, explaining the link between CPPD and hypomagnesaemia (Richette et al, 2007). Hypercalcaemia due to familial primary hyperparathyroidism or hypocalciuric hypercalcaemia increases the $[Ca \times PPi]$ product. In addition cartilage damage is also likely to play a role in CPPD as suggested by the association of CPPD with previous traumatic or surgical trauma of the involved joint (Doherty et al, 1982; De Lange and Keats, 1985).

Figure 1 Radiograph of an anatomical slice of the knee joint showing calcium pyrophosphate deposition within the femur cartilage (FC), tibial cartilage (TC) and the meniscus.

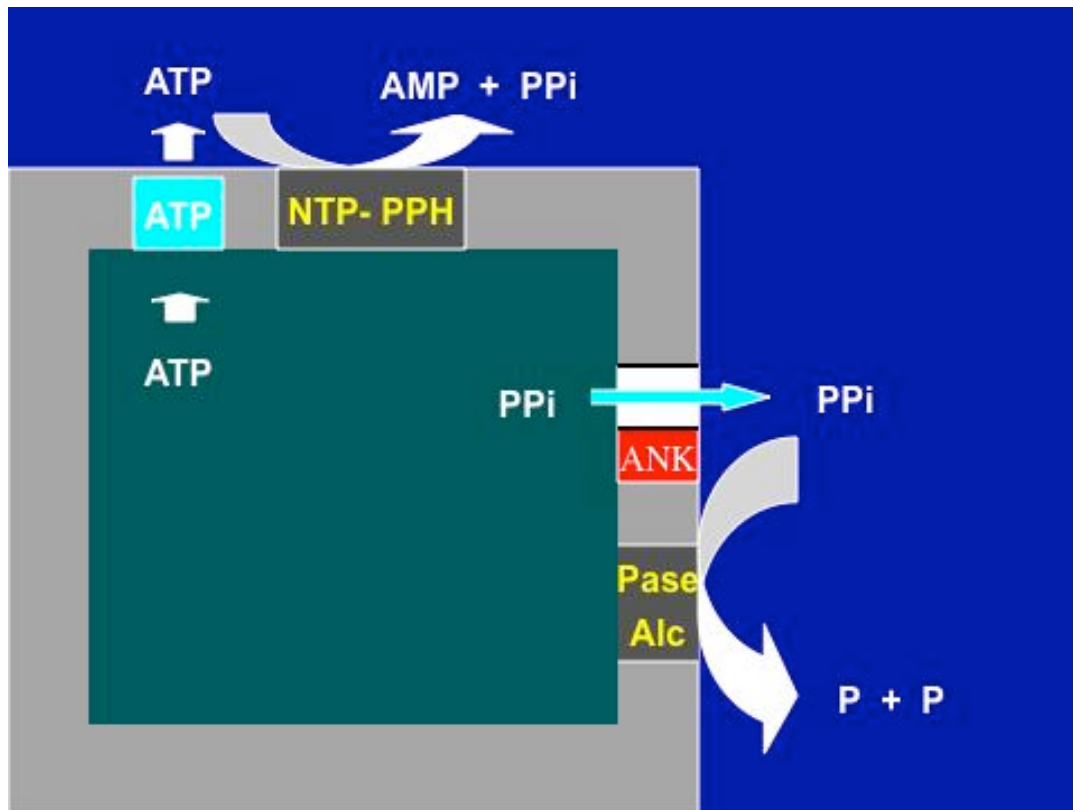

Figure 2 Metabolism of extracellular pyrophosphate (PPi).

Clinical features of CPPD are probably due to the interactions of various cells with CPP crystals. CPP crystal-induced acute inflammation follows patterns similar to monosodium urate crystal-induced inflammation, including activation of interleukin 1, which seems to play an important part in triggering inflammation (Martinon *et al*, 2006) and could become a target for treatment. CPP crystals may also interact with synovial fibroblasts, leading to the release of metalloproteinase and other mediators involved in joint destruction (Cheung *et al*, 1981).

2.6 Clinical presentation

CPPD is most frequently asymptomatic. CC is often recognised incidentally on radiographs of elderly healthy individuals. Therefore it should not be too easily considered as a certain cause of joint symptoms.

Acute CPP crystal arthritis has been called ‘pseudo-gout’ because it was mistaken for gout before the introduction of synovial fluid microscopy and discovery of monosodium urate and CPP crystals, which then made it possible to discriminate between these two conditions. It is a common cause of acute arthritis in the elderly, which has to be distinguished from other causes of severe acute monoarthritis such as septic or reactive arthritis. Similarly to a gout flare, acute CPP crystal arthritis has a brusque onset, and is self-limiting. It most often affects the knee, with other commonly affected joints being the wrist, ankle and shoulder. Triggering factors include trauma, intercurrent illness or surgery, bisphosphonate infusion (Wendling *et al*, 2008), parathyroidectomy (White *et al*, 1988) (which may dissolve crystal deposits by lowering calcium levels)

and joint lavage of the affected joint. Arthroscopic lavage of a joint with pre-existing CC has been estimated to provoke acute CPP crystal arthritis in 26% of cases, probably by promoting crystal shedding in the joint space (Pasquetti *et al*, 2004). Hyaluronate intra-articular injection has been repeatedly reported as a triggering factor (Dilsa *et al*, 1999), though this has been disputed (Punzi *et al*, 2000). Granulocyte colony stimulating factor has also been reported to favour acute CPP crystal arthritis in patients with neutropenia, a finding consistent with the important role of polymorphonuclear cells in the genesis of crystal-induced acute inflammation (Ames and Rainey, 2007). Severe inflammation of a large joint may be accompanied by fever and simulate a bacterial infection. Septic arthritis and CPP crystal arthritis can coexist and so bacteriological studies should be conducted even in SF exhibiting CPP crystals (Zhang *et al*, 2010). Oligoarticular or even polyarticular acute CPP crystal arthritis may occur and the inflammation can also be less intense or acute. In superficial joints, such as the wrist, erythema and swelling may be prominent. Attacks of arthritis are generally intermittent with long intercritical periods, but some patients have frequent attacks affecting the same, or a different, joint each time. As the pattern can vary it is sensible to look for CPPD in all cases of undiagnosed more or less inflammatory arthropathy, either intermittent or persistent, with or without associated OA.

Chronic CPP crystal inflammatory arthritis may mimic RA (McCarty 1976), with longstanding bilateral and symmetrical synovitis, frequently involving the wrists and finger joints and tendon sheaths, associated with increased acute phase reactants and increased cellularity of the SF. Radiographs differ from those for RA and typically exhibit CC and fine subchondral bone sclerosis underlining bone contours, epiphyseal geodes and frequent osteophytosis, with no marginal erosion. SF analysis allows appropriate diagnosis by demonstrating the presence of CPP crystals. Predominant involvement of proximal joints may also mimic polymyalgia rheumatica, a disease which also predominantly affects the elderly (Pego-Reigosa *et al*, 2005).

OA with CPPD usually differs little from OA without CPPD. Prospective studies have been unable to show any difference in the outcome of OA according to the presence of CPPD (Neogi *et al*, 2006; Viriyavejkul *et al*, 2007). CPP crystals are often identified in OA SF and may be only an epiphenomenon, secondary to cartilage damage in OA (Nalbant *et al*, 2003). However, some sites, such as the ankles, elbows, wrists and shoulders seem to be more frequently involved in CPPD than in 'primary' OA. Involvement of the trapezioscapoid joint has been strongly associated with CPPD, and may suggest this diagnosis, especially when the first carpometacarpal joint appears normal (Peter *et al*, 2001). Large or multiple small subchondral bone cysts can be found in OA with CPPD, particularly at the wrist, where radioulnar arthropathy, non-traumatic scapholunate dissociation and carpal collapse can also be seen (Resnick and Utsinger, 1974; Bourqui *et al*, 1983). Osteophytosis has also been reported to be associated with CC (Neame *et al*, 2003).

Destructive arthropathies have been described in elderly women with CPPD (Richards and Hamilton, 1974; Menkes *et al*, 1976). Several joints are often involved—in particular, the hip, knee, spine, wrist and shoulder. Joint space narrowing is associated with subchondral bone destruction, which may lead to a pseudo-Charcot

joint picture. Progression of destruction can be rapid: the so called rapidly destructive OA of the hip has been linked to CPPD (Menkes *et al*, 1985).

Haemarthrosis is a classic feature of CPPD. Bleeding in the joint can be recurrent and seems to follow bone erosion.

Spinal involvement of CPPD may be restricted to asymptomatic deposits in intervertebral discs. These CPP deposits can also be responsible for acute or subacute inflammatory episodes. Inflammation can be associated with destructive changes suggestive of infectious discitis. Imaging studies show the absence of abscess. A reassuring vacuum phenomenon is frequently exhibited by CT scan or plain radiographs (lateral extension views). Interapophyseal joint involvement can be responsible for joint erosion and instability, spondylolisthesis and sometimes large cysts of the pedicles. Cervical spine involvement can be associated with cervical myelopathy, sometimes related to dural CPPD. The craniocervical hinge can be involved and CPPD is together with basic calcium phosphate deposition disease a source of the crowned dens syndrome, characterised by calcium deposits around the dens and responsible for acute pain of the upper cervical spine and occiput (Feydy *et al*, 2006; Salaffi *et al*, 2008). CPP deposits in the transverse ligament can be associated with erosion of the adjacent dens and type II fracture (Kakitsuba *et al*, 2000).

Tendons and fascia can be affected by CPPD. Tendon deposits appear in radiographs as fine linear calcifications starting at a distance from the bone attachment. Their appearance is therefore very different from the rounded opacities of basic calcium phosphate deposition. Achilles, quadriceps and gastrocnemius tendons are often affected (Gerster *et al*, 1977; Tang *et al*, 1996). Plantar or finger flexor fascia can also be involved. An ultrasound scan is a useful tool for detecting CPP deposits in tendon or fascia (Falsetti *et al*, 2004). These deposits are most frequently asymptomatic, although local pain, nerve entrapment syndromes and finger extensor tendon rupture have been associated with tendon or fascia CPPD (Gerster *et al*, 1980; Patrick *et al*, 1988; Waguri-Nagaya *et al*, 2001).

Tumoural deposits of CPP crystals are rare but have been reported in various sites: fingers, knees, hips, temporomandibular joints, most frequently in patients lacking CC (Sissons *et al*, 1989; Ishida *et al*, 1995). In some instances deposits appear to follow a cartilaginous metaplasia of the synovium. Others, such as those in the finger pulp, arise far from the joints. Rare CPPD in the retina, dura or other extra-articular sites has also been reported.

2.7 Diagnosis

As emphasised by the EULAR recommendations for the diagnosis of CPPD (Zhang *et al*), identification of CPP crystals in synovial fluid or joint biopsy specimen allows a definite diagnosis. CPP crystals are poorly birefringent and are better seen by regular light than by polarising microscopy (Ivora *et al*, 1999). Under

compensated polarising light microscopy, crystals appear as positively birefringent. They can be observed, in particular, in the knee in the SF of asymptomatic joints (Martinez and Pascual, 2005). The demonstration of typical CC by radiographs (figure 3) is of good diagnostic value but may lack sensitivity (Utsinger *et al*, 1975). Radiographs of knees are the most frequently positive. Other joints such as the pubic symphysis, wrists, shoulders, or others less frequently, display CC on radiographs. Ultrasound scanning appears to be a promising tool to provide evidence of CPP deposits and may be more sensitive than radiography, in particular at the wrist (Frediani *et al*, 2005; Filippou *et al*, 2007) and at the knee (Barskova *et al*, 2013). Although metabolic predisposition is rare, patients with young age at onset (age under 55 years) or florid polyarticular chondrocalcinosis should be screened for primary hyperparathyroidism (serum calcium, parathyroid hormone), haemochromatosis (ferritin), hypomagnesaemia (serum magnesium) and hypophosphatasia (alkaline phosphatase) (Zhang *et al*, 2011).

Figure 3 Chondrocalcinosis.

2.8 Management

Very few studies have dealt with CPPD management (Zhang *et al*, 2011). No drug has been shown to influence CPP deposition and therefore CPPD management remains purely symptomatic. Magnesium supplementation led to reduction in CC in one hypomagnesaemic patient (Runeberg *et al*, 1975) and can be recommended in cases of hypomagnesaemia. Treatment of underlying hyperparathyroidism or haemochromatosis does not seem to affect the course of CPPD (Barskova *et al*, 2013). In vitro, probenecid reduces the activity of the ANKH transporter (Ho *et al*, 2000) but has not been tested in human CPPD.

Acute CPP crystal arthritis is best treated by rest, local ice packs, SF aspiration (which also allows SF examination and identification of CPP crystals) and intra-articular steroid injection (Zhang *et al*, 2011). Colchicine or non-steroidal anti-inflammatory drugs (NSAIDs) can be used but may be poorly tolerated by the elderly. Moreover, support for their use is mainly indirect, extrapolated from studies in acute gout attacks. Adrenocorticotrophic hormone and parenteral or oral glucocorticoids (at an oral dose equivalent to 30–35 mg

on the first day, then tapered over a few days) can be used for joints which are difficult to inject in patients intolerant of, or refractory to, colchicine and NSAIDs (Ritter et al, 1994; Werlen et al, 1996; Roane et al, 1997). Low-dose colchicine (1 mg/day) may be used as a preventative treatment in patients with frequently relapsing flares (Alvarellos and Spilberg, 1986). Interleukin 1 inhibitors are active on crystal-induced inflammation and could become a therapeutic alternative in patients with contraindication to colchicine, NSAIDs and steroids (Announ et al, 2009; Moltó et al, 2012). Management of OA with CPPD does not differ from that of OA without CPPD. Chronic CPP crystal inflammatory arthritis can be improved by low-dose colchicine (Das et al, 2002), NSAIDs, steroids and hydroxychloroquine (Rothschild and Yakubov, 1997) or methotrexate (Chollet-Janin et al, 2007). Hydroxychloroquine was shown to be helpful in one placebo-controlled study (Rothschild and Yakubov, 1997). Methotrexate has been tested in a double-blind, placebo-controlled crossover study, but the results have been disappointing with no statistically significant reduction in the DAS44 score, pain level or secondary outcome (Finckh et al, 2014). Radiation synovectomy has been shown to improve chronic CPPD with OA (Doherty and Dieppe, 1981). The risk/benefit ratio of these drugs should be considered cautiously as CPPD most frequently affects the elderly. Asymptomatic CPPD does not require any treatment (Zhang et al, 2011).

SUMMARY POINTS

- **CPPD is mainly a disease of the elderly. It is usually a sporadic disease but its presence requires consideration and investigation for primary hyperparathyroidism, haemochromatosis and hypomagnesaemia.**
- **Definite diagnosis is obtained by identification of CPP crystals in SF. X-ray demonstration of CC is most frequently obtained by radiographs of the knees; it is highly suggestive of CPPD but may lack sensitivity. US scan appears to be a promising diagnostic tool.**
- **The most frequent CPPD presentation is asymptomatic CC, which requires no treatment.**
- **Demonstration of CPP crystals in an OA joint is most likely an incidental finding with no implication for prognosis.**
- **Treatment of acute CPP crystal arthritis mainly relies on joint aspiration and intra-articular steroid injection**

3 Basic calcium phosphate crystal deposition disease

LEARNING OUTCOMES

- Describe the natural course and the clinical presentations of basic calcium phosphate crystal deposition disease
- To recognise localised periarticular disease using X-rays or sonography
- Use the principles of its management

3.1 Introduction

Basic calcium phosphates (BCP) crystals, in contrast to acidic calcium phosphates such as brushite, form at basic pH and include apatite, octacalcium phosphate and tricalcium phosphate (McCarty et al, 1983*).

Deposits were long recognised in tendons and bursae where they are common and easy to demonstrate by X-ray examination. The demonstration of intra-articular BCP crystals came later (Dieppe et al, 1976; Schumacher et al, 1977) and remains difficult as crystals are too small to be identified by light microscopy.

3.2 Periarticular BCP deposits

3.2.1 Epidemiology and predisposing factors

Calcific tendinitis or bursitis is common, especially in the shoulder. In 1941 a study of a large office worker population of North America estimated that the prevalence of deposits discernible by X-rays in the shoulder was 2.7%. Prevalence was highest in middle-aged women (19.5% between 31 and 40 years), and nearly half of the deposits were bilateral (Bosworth, 1941). Shoulders are affected in roughly 60% of patients, followed by the hip and elbow, wrist, hand (Gondos, 1957; Amor et al, 1977). Calcifications can be observed in almost any joint. They are frequently multiple (Welfling et al, 1965; McCarty and Gatter, 1966; Amor et al, 1977), leading to the hypothesis that systemic factors play a role in the pathophysiology. Familial occurrence has been reported (Cannon and Schmid, 1973; Hajiroussou and Webley, 1983). An association with diabetes mellitus has

been observed (Mavrikakis et al, 1989). Calcifications can arise in the presence of various connective tissue diseases, mainly scleroderma and dermatomyositis/polymyositis (Reginato and Schumacher, 1977). Rarely, deposits appear to be favoured by the elevation of serum [Ca \times P] product observed in vitamin D intoxication, primary hyperparathyroidism and terminal renal failure (Bardin et al, 1988; Moskowitz et al, 1969*). Local factors have been incriminated at the shoulder. Deposits mainly involve the supraspinatus tendon at approximately 1 cm from its insertion into the greater tuberosity of the humerus, which is considered a critical zone of relative avascularity (Rathbun and Macnab, 1970). BCP deposition could follow tendon injury and necrosis or cartilaginous metaplasia of the tendon, induced by ischaemia (Uthoff et al, 1976; Uthoff and Sarkar, 1989*). It can also follow tissue damage caused by local steroid injections (Dalinka et al, 1984*).

3.2.2 *Natural course*

It has long been noted that deposits can spontaneously disappear (Bosworth, 1941). The natural history seems to follow several phases (Hayes and Conway, 1990). In the first phase, deposits are entirely contained in the tendon and usually do not cause any symptoms (asymptomatic phase). The second phase is characterised by growth of the deposit, which becomes liquefied, and may lead to enlargement of the tendon and impingement-like symptoms (mechanical phase). In the third phase, crystals reach the periphery of the tendon and/or the calcification ruptures into an adjacent bursa. Crystals therefore come into contact with cells, leading to acute painful episodes (inflammatory phase). Rupture into the bursa favours resorption of the calcification, which may then disappear.

3.3 Clinical presentation

Most periarticular BCP deposits are asymptomatic.

3.3.1 *BCP crystals*

BCP crystals can cause acute microcrystalline tendinitis or bursitis (McCarty and Gatter, 1966; Cannon and Schmid, 1973; Amor et al, 1977). Pain is of abrupt onset and very intense. If the calcification is superficial—that is, in a finger or a toe, erythema and swelling can develop. Untreated, the episode lasts from a few days to a few weeks. Radiographs usually demonstrate the causative calcification, which may, however, have disappeared during the acute attack. A history of recurrent flares and demonstration of calcifications in other sites, such as the hips, usually allows the correct diagnosis to be made. Arthrocentesis may be required to rule out septic arthritis. Acute attacks may affect nearly every joint, including finger joints (Selby, 1984*) and the great toe. Gout is another differential diagnosis. Whereas gout attacks usually involve men, BCP-induced podagra is most commonly seen in young or middle-aged women (Fam and Rubenstein, 1989*).

3.3.2 Chronic pain

BCP tendon calcification can cause chronic pain, which can be polyarticular when calcifications are multiple; multiple tendon calcifications should be included in the multiple regional pain investigation, especially in young or middle-aged women. Chronic pain is particularly common at the shoulder. One small study disclosed rotator cuff calcification in 14 of 34 shoulders that were painful for more than a year (Caroit et al, 1978). Pain can be due to chronic tendonitis or enlargement of the tendon, leading to subacromial impingement. The latter mechanism is supported by the frequent finding of a painful arch in anterior arm elevation between 70 and 110° (Kessel and Watson, 1977).

3.3.3 Bone erosions

Bone erosions have been discussed by Fritz et al (1994)* and Kraemer and El-Khoury (2000). Para-osteal calcifications may be associated with adjacent cortical erosion, particularly at the diaphyses of the proximal femur and humerus. Clinical presentation is usually dramatic with intense pain, marked tenderness and frequent swelling of the affected area. The erythrocyte sedimentation rate and C-reactive protein are raised. A bone scan shows an increased uptake of the isotope, and T2-weighted MRI an increased signal intensity of the soft tissues and bone marrow in the same area. Radiographs and CT scan demonstrate para-diaphyseal calcification and an adjacent cortical erosion. Over a few weeks or months, the calcification, then the cortical erosion, disappear and the patient usually recovers completely.

3.3.4 Axial involvement

BCP deposits can involve the longus coli tendon, anterior to the C2 and C1 vertebral bodies. Acute attacks are responsible for severe pain of the upper cervical spine and pharynx, which may be associated with fever and dysphagia, leading to suspicion of a retropharyngeal abscess. Radiographs and CT scan demonstrate the longus coli calcification, associated with swelling of the prevertebral soft tissue (Hall et al, 1986).

Disc deposits of BCP (Taylor and Little, 1963) are often localised inside the nucleus pulposus or adjacent to the anterior aspect of the disc and are most frequently asymptomatic, although they can trigger acute episodes of spinal pain (Amor et al, 1977). Disc calcification is a key feature of ochronosis and has been shown to be composed of BCP (Lagier and Sit'aj, 1974).

BCP deposits appear to be a cause of the crowned dens syndrome, which can also occur owing to calcium pyrophosphate deposition. Both types of crystals can give rise to acute inflammatory episodes of the craniocervical hinge (Bouvet et al, 1985*; Malca et al, 1995).

3.3.5 Diagnosis

Diagnosis of periarticular calcifications relies on imaging techniques using X-rays or ultrasound (figure 1). Plain radiographs show homogeneous ovoid opacities, without a cortex or trabeculation, in contrast to heterotopic ossification or accessory ossicles. Ultrasound is valuable, picking up even small deposits (Farin and Jaroma, 1995; Papatheodorou et al, 2006). By allowing precise localisation of calcification in the tendon and providing information on its consistency (liquid or solid), an ultrasound scan has also been found helpful for guiding needle aspiration of the deposit (Farin et al, 1996a).

Figure 1 Left: Subacromial calcification. Right: Calcifications by the metacarpophalangeal joints.

3.3.6 Management

Acute inflammatory episodes are best treated by local ice, rest, short immobilisation of the affected joint and local steroid injection. Non-steroidal anti-inflammatory drugs (NSAIDs) or systemic steroids at a starting dose of 30 mg equivalent prednisone/day are also effective. Colchicine can be used, in particular to prevent frequently relapsing flares, at a dosage of 1–2 mg/day. A recent pilot study favours the efficacy of anakinra, which can therefore be used in patients for whom NSAIDs and steroids are contraindicated (Zufferey and So, 2013*). There are no controlled data on these treatments, which are supported only by experience. A rare underlying hyperphosphataemic or hypercalcaemic disease should be treated.

Removal of the deposit can be considered in patients with chronic pain, particularly at the shoulder. X-ray or ultrasound-guided aspiration and lavage of the calcification, often followed by local steroid injection, is an effective procedure (Farin et al, 1996b; Aina et al, 2001; del Cura et al, 2007). Disruption of BCP crystal deposit during the procedure may trigger an acute inflammatory episode, which may help to remove the BCP deposit. Removal has also been performed by open surgery, which has now been replaced by arthroscopy. Extracorporeal shock wave therapy has been the topic of a large number of open studies and of several randomised controlled trials, which have proved its efficacy (Rompe et al, 1995; Ebenbichler et al, 1999; Loew et al, 1999; Speed et al, 2002; Gerdesmeyer et al, 2003).

3.3.7 Intra-articular BCP deposits

BCP crystals are difficult to identify in synovial fluid (SF) because they are too small to be detected by polarising light microscopy. They form non-birefringent rounded aggregates, which can be stained by a calcium stain, the alizarin red S stain (Paul et al, 1983*). This test is not specific for BCPs as other calcium crystals can also be stained. Transmission (or scanning) electron microscopy coupled with energy dispersive analysis is necessary for definite diagnosis. Such techniques are not available everywhere and are time consuming, making them inappropriate for routine use.

Intra-articular BCP crystals can induce acute arthritis (Schumacher et al, 1977), sometimes owing to the rupture of a periarticular calcification into the joint cavity (Gerster and Fournier, 1995). The term Milwaukee shoulder has been coined by McCarty et al, to denominate a destructive arthropathy of the shoulder associated with a large rotator cuff tear, periarticular calcification and a paucicellular and frequently haemorrhagic SF containing BCP crystals (McCarty et al, 1981). Collagenase and neutral protease were identified in the SF (Halverson et al, 1981), leading to the hypothesis that BCP crystals can induce joint destruction, since calcium crystals have been shown in vitro to induce release of these enzymes from synovial cells (Ea et al, 2011*). However, the clinical presentation of Milwaukee shoulder is very close to cuff tear arthropathy (Neer et al, 1983), and mechanical factors are likely to play an important role. Moreover, the finding of apatite in the SF of a destructive arthropathy can be considered as a non-specific finding, resulting from crystal shedding from the eroded subchondral bone. Finally, apatite crystals are often found in osteoarthritic (OA) SF (even more frequently than CPP crystals) and are almost constantly present in the remaining cartilage of OA joints examined at the stage of articular prosthesis (Ea et al, 2011*). The role these crystals might play in the OA process remains under investigation (Ea et al, 2011*).

IN-DEPTH DISCUSSION I

**Essentials of crystal detection and identification in
synovial fluid**

Identification of monosodium urate (MSU) crystals and calcium pyrophosphate (CPP) crystals provides an aetiological definitive diagnosis of gout and CPP crystal arthritis. The diagnosis of these two conditions is often approached clinically, and when the disease has a 'typical' presentation (such as repeated podagra in a hyperuricaemic patient or an acute knee arthritis in a patient with 'typical' chondrocalcinosis) the diagnosis is usually correct. But as the presentation diverges from the most characteristic one and in the absence of synovial fluid (SF) analysis for crystals the possibility of error increases, and requires a diagnostic investigation which is not always simple or conclusive. It is in such patients where the diagnosis is less evident that other doctors usually consult rheumatologists, and they expect—and know we can provide—an evidence-based diagnosis for crystal arthritis. Other crystals visible by the optic microscope are of limited interest. This subject is dealt with in greater depth in the EULAR online course.

The size of MSU and CPP crystals allows detection and reasonable provisional identification with an ordinary optical microscope (Pascual et al, 1989). Fitting the microscope with polarised filters—analyser and polariser—(simple polarised microscope) allows detection/identification by shape + birefringence; this microscope is commonly used in pathology departments. Finally, adding a first-order red compensator to the system (compensated polarised microscope) allows more definitive identification of both crystals; this last setting remains the standard for crystal identification in SF (Phelps et al, 1968). After training, crystal identification in SF is consistent (Lumbreras et al, 2005). Beginners fear they may have difficulty in differentiating MSU and CPP crystals but, in general, most analysts find the appearance of the crystals is different and recognise them at first glance. Training consists in becoming familiar with both crystals and then recognising them in new samples. An ordinary microscope fitted with the proper filters (some most popular brands provide sets of these) is the correct tool. A ×600 lens allows better vision and, for learning, a ×1000 lens allows a closer look (especially important in the polymorphic CPP crystal) and familiarisation with the crystals. Finally, a bright halogen light or similar is important for observation under polarised light—especially simple polarised light—since the strength of the brilliance of the crystal depends on it. Beginners should first become familiar with the use of the microscope—focusing, regulating the condenser and so on—and also with other elements in SF such as cells and other occasional common artefacts—for example, cotton fibres, starch from gloves or dust particles.

Both types of crystals are seen in SF taken from joints affected by an acute attack and in gout also in SF from previously inflamed joints if the patients have not received urate-lowering treatment. CPP crystals have also been regularly identified in SF samples from previously inflamed joints—a treatment which can eliminate the crystals from the joints is much needed. In gout, crystals are regularly recovered by needling a tophus.

1. With an *ordinary microscope* both MSU and CPP crystals are easily seen and with experience can be identified by their shape, and can be used when polarising microscopes are unavailable.

(i) All MSU crystals are needle shaped, their size varying from very small to about twice the diameter of a white blood cell both intracellularly and extracellularly (figures 1A, B). Often crystals are abundant and are easily seen already in the first $\times 400$ microscope field examined; when scarce, detection of the crystals with this method may be problematic.

(ii) CPP crystals are polymorphic. Their shape varies from a rhombus to thin needles; rods or thick needles and parallelepipeds are intermediate forms (figures 2A–D, 3A, C). Sizes vary from very small to about twice the diameter of the usual white blood cell. Extracellular crystals are seen but it is worth checking for crystals inside cells where they are very commonly found. Here using a magnification of $\times 1000$ has an advantage in enabling acquaintance with the crystals, facilitating later recognition. Examination with the ordinary light microscope allows a reasonable detection and identification of MSU and CPP crystals and it is worth doing if no polarised microscope is available.

Figure 1: Bright field microscopy. (A) $\times 400$; (B) $\times 1000$ monosodium urate (MSU) crystal. MSU crystals are well distinguished and all crystals are needle shaped. If abundant (and often they are) their presence is immediately obvious.

Figure 2: Bright field microscopy. (A, B) $\times 400$; (C, D) $\times 1000$. (A) Abundant calcium pyrophosphate (CPP) crystals; (B) single parallelepiped crystal. (C, D) To become familiar with the crystals $\times 1000$ magnification offers greater detail. Photomicroscopy offers only a very thin plane on focus. At the microscope the fine-focus knob allows all the structure to be brought into focus and seen more clearly.

Figure 3: (A, C) Bright field microscopy $\times 600$. Calcium pyrophosphate (CPP) crystals are seen and distinguished by shape. (B, D) Same as A and C after crossing the polarised filters for simple polarised microscopy. (E) Simple polarised microscopy $\times 1000$. These figures show the range of birefringence of CPP crystals from none to quite brilliant—seldom reaching that of monosodium urate crystals. About 80% of CPP crystals do not show any birefringence. (For photography, polarised filters are not totally crossed to allow some background detail.)

2. The *simple polarised microscope* allows detection and identification by birefringence.

- (i) All *MSU crystals* are strongly birefringent and shine brightly against the dark background of the microscope field (which results from crossing the polarised filters) (figures 4A–C). This setting is the ideal for finding MSU crystals if they are few, since owing to their brightness they are easily seen in the dark microscope field. Small MSU crystals may not show birefringence. Additionally, birefringence cannot be seen when the long axis of a crystal is oriented parallel to the axis of either of the polarised filters (position of extinction).
- (ii) Only about one-fifth of *CPP crystals* show any birefringence (Ivorra *et al*, 1999) and, in general, it is much fainter than that of MSU crystals. Therefore, absence of birefringence should not be taken as an indicator of the absence of CPP crystals (figures 3A–E). The often very thin rods or even needle-shaped CPP crystals usually show no birefringence, allowing easy distinction from MSU crystals.

3. *Compensated polarised microscopy* is the standard tool for crystal analysis in SF. It determines the sign of birefringence, which depends on whether the wavelength traversing the long axis of the crystal has increased or reduced when polarised light traverses them.

- (i) *MSU crystals* show negative birefringence, or elongation, recognised because the long axis of the crystal is yellow when parallel to the compensator axis (or direction of slow vibration)—most often marked with an arrow and the Greek letter λ , and blue if perpendicular to it (figures 5A–E).
- (ii) *CPP crystals* are positively birefringent, showing a lighter yellow colour when the long axis is perpendicular to the compensator axis, and lighter blue than MSU crystals if parallel (figures 6A–C).
- (iii) All MSU crystals behave similarly in this system and being all similarly birefringent all clearly show their negative birefringent sign. Not all CPP crystals clearly show their birefringent sign; many do not show birefringence on simple polarised microscopy and may not show it with compensated polarised microscopy. Other CPP crystals because of their shape are difficult to orient in relation to the compensator axis, and occasional crystals may show negative birefringence.

Figure 4: Simple polarised microscopy. (A, C) $\times 400$; (B) $\times 600$. Monosodium urate crystals are easily seen because of 'shine' due to their strong birefringence. (A, B) Synovial fluid sample; (C) crystals obtained by needling a tophus; these crystals are usually larger than those seen in synovial fluid. (For photography, polarised filters are not totally crossed to allow some background detail.)

Figure 5: Compensated polarised microscopy. The arrow (λ) indicates the direction of the axis of the compensator. (A, B) $\times 400$ Synovial fluid: single monosodium urate (MSU) crystal oriented perpendicular and parallel to the axis of the compensator. (C) $\times 400$ Synovial fluid: multiple MSU crystals (and cells) showing yellow or blue colour, depending on their orientation. (D, E) $\times 400$ MSU crystals from needling two different tophi. Size can be much larger than crystals found in synovial fluid. These figures show the appearance of MSU crystals as seen by compensated polarised microscopy.

Figure 6: Compensated polarised microscopy $\times 1000$. (A, B) Characteristic parallelepipedic calcium pyrophosphate (CPP) crystals showing positive elongation (birefringence): blue if parallel and yellow if perpendicular to the axis of the compensator (arrow (λ)). (C) Compensated polarised microscopy $\times 1000$. These abundant CPP crystals show the frequent difficulty of determining the sign of elongation of crystals whose identity is clear from their shape. Crystals are here shown at $\times 1000$ for educational purposes. Usually observation is at $\times 400$ —or better at $\times 600$ —which allows good distinction of the crystals.

The sample to be examined should be fresh, or at least examined during the day it is obtained, and if possible kept at 4°C in a refrigerator to avoid decay of the cells, which is important, especially for the frequently intracellular CPP crystals. For examination a small drop of SF fluid (a large drop makes the preparation too thick) should be placed on a glass slide and a cover slip paced over it. No fixation or staining is required. The time spent looking for crystals before deciding that a preparation is negative has not been critically ascertained; however,

in most preparations crystals are abundant and often seen in the first field examined. Occasionally, fluids require a prolonged examination.

If training with a compensated polarised microscope is started without first acquiring experience with an ordinary microscope and then a simple polarised microscope this may cause problems, as a compensated polarised microscope can be a difficult instrument to use.

IN-DEPTH DISCUSSION II

Diagnosis of monoarthritis

The presentation of a patient with non-traumatic acute monoarticular arthritis is a common clinical scenario for which there is a wide differential diagnosis. Crystals induced arthritis, reactive arthritis, rheumatoid arthritis, Lyme disease, pigmented villonodular synovitis, haemarthrosis, cellulitis, transient synovitis of unknown aetiology and a variety of systemic or local diseases can result in a painful swollen peripheral joint. Arriving at a correct diagnosis is crucial for appropriate treatment particularly for non-gonococcal bacterial arthritis; promptly distinguishing between joint infection and other cause of monoarthritis is vital because septic arthritis can be devastating. Indeed, a delay in diagnosis and treatment of septic arthritis can lead to severe cartilage and joint destruction associated with high morbidity and mortality despite the use of adequate antibiotic therapy. Furthermore prognosis worsens with an increasing time interval between onset of infection and treatment (Margaretten et al 2007, Tarkowsky, 2006). The initial approach to diagnosing the underlying cause of an acute monoarthritis involves taking a careful history and examination. The history should include a review of symptoms, previous joint disease or family history of such, concurrent illnesses, past sexual contacts, travel, gastrointestinal and genitourinary infections, psoriasis, medication use or other risk factor for crystals arthritis (diuretic therapy, hypertension, obesity, renal insufficiency), chondrocalcinosis (recent medical or surgical illness, old age, history of hyperparathyroidism, haemochromatosis or inborn errors of metabolism) or septic arthritis, (age older than 80 years, diabetes mellitus, rheumatoid arthritis, HIV infections or immunosuppressed status, recent joint surgery, evidence of infection outside the joint). The physical examination should include looking for other involved joints and for systemic manifestation of predisposing diseases. On their own, however, the patient's history and physical examination are usually not sufficient to make a diagnosis.

The most common underlying cause of an acute monoarthritis includes crystal arthritis, septic arthritis and reactive arthritis. Reactive arthritis (ReA) develops about 1-6 weeks following an enteric (*Salmonella*, *Shigella*, *Campylobacter* and *Yersinia*) or urogenital (*Chlamydia trachomatis*) infection and a typical presentation includes asymmetric monoarthritis of lower limb joints. In the early stages of ReA synovial cell count can be quite high and polymorphonucleate leucocytes can dominate the picture. A history of gastroenteric illness preceding the arthritis, young age, lower limb involvement and unsafe sexual intercourse would favour the diagnosis of ReA. Extra-articular additional symptoms can be found (ocular and skin symptoms). Nevertheless infection can be asymptomatic, particularly in women (Chlamydia) (Kumar et al, 2014) and most patients do not have the classic triad of symptoms involving the urethra, conjunctiva and synovium (Mathews and Ravindran, 2014).

Gout, pseudogout and septic arthritis appear quite similar on physical examination. Established risk factors for septic arthritis include age older than 80 years, diabetes mellitus, rheumatoid arthritis, recent joint surgery, joint prosthesis skin infections and HIV infections (Margaretten et al, 2007). Risk factors for gout include hypertension, obesity, metabolic syndrome, renal insufficiency, type 2 diabetes mellitus, alcohol abuse and diuretic therapy. Direct joint trauma, intercurrent medical illness (i.e. infection) or surgery may trigger acute pseudogout in elderly patients.

Fever may or may not be present in these conditions and does not help to differentiate between them. Fever, sweats and rigours are more common in septic arthritis but have a low sensitivity for the diagnosis (57%, 27% and 19% respectively) (Margaretten et al, 2007, Nolla et al 2015). Peripheral blood measurement of white blood cells, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) have poor diagnostic utility because they can be elevated in various pathological conditions including not only crystal arthritis but also inflammatory joint disease. Moreover, their absence does not exclude the diagnosis of septic arthritis. Serum urate is usually elevated in patients with gout. However, during the acute attack serum urate can be within the normal range due to increased renal excretion of uric acid (release of ACTH from adrenal stimulation during a painful attack) and increased inflammatory activity (pro-inflammatory cytokines IL6 and IL1 β are directly correlated with lower uric acid levels) (Bădulescu M et al. 2013). Furthermore, an elevated urate level in serum per se is not a confirmatory test for gout. Therefore, clinical and serum findings alone are not reliable for the diagnosis.

The key to establish the diagnosis is prompt microscopic analysis and culture of synovial fluid aspirated from the affected knee. Aspiration of synovial fluid should be made always before antibiotic treatment is started. Once aspirated joint samples are obtained, it is imperative that they are quickly transported to clinical microbiology and not be allowed to stand for a long time without processing or culturing. The injection of synovial fluid into blood cultures bottles can increase the detection of pathogens. If synovial fluid cannot be obtained with closed needle aspiration, for joints not easily accessible as hip, shoulder and sacroiliac joint, arthrocentesis must be done by imaging guidance. If septic arthritis is suspected blood should always be cultured before starting antibiotic treatment to increase the chances of obtaining causative organisms. Indeed, in 9% of patients blood cultures are the only source of a positive microbiological diagnosis. The synovial fluid must be analysed for gram stain, white blood cells count (WBC) and differential and cultured for bacteria. A negative Gram stain does not by itself rule out septic arthritis since the sensitivity of the synovial fluid Gram staining is limited and it is positive in 71% of Gram positive septic arthritis, 40-50% of cases of Gram negative septic arthritis and in < 25% of cases of gonococcal septic arthritis (Garcia-De la Torre and Nava-Zavala, 2009). Culture is positive in 50% of patients. In cases where there is a high index of suspicion of septic arthritis though with a negative culture, a synovial membrane biopsy and tissue culture may be required to identify the pathogen. If an abnormal and/or slow growing organism is suspected like *Brucella* or *Neisseria gonorrhoeae*, the laboratory should be warned since these organisms often require a special culture medium and extended culture time for its growth. Acute microcrystalline arthritis and septic arthritis may have similar values for WBCs. The concentration of synovial white blood cells (WBCs) in septic arthritis is usually increased; a count of $> 50 \times 10^9/L$ with $> 90\%$ of polymorphonuclear cell increase the likelihood ratio of septic arthritis. The higher the synovial fluid leukocytes count the greater the likelihood of septic arthritis: more than 100,000/ mm³ WBCs has a likelihood of 7.7 for the diagnosis (Smith et al, 2006, Mathews et al, 2008). Nevertheless, lower cell counts (below 50,000 cells/mm³) are not rare.

The diagnosis of gout is made by identifying monosodium urate crystals in the synovial fluid. Rarely gout and septic arthritis coexists making it essential to analyse the synovial fluid for both crystals and the presence of microorganisms (Lim et al, 2015). There are several possible mechanisms by which gout may increase the risk of septic arthritis: a) joint damage resulted from release of IL-1, inducible nitrox oxide synthetase, MMP and osteoblast activation after urate deposition can contribute to an increase risk of development of septic arthritis similar to joint damage associated with rheumatoid arthritis (Mathews, et al 2010), b) subcutaneous tophi predisposes patients' to skin breakdown and ulceration and direct inoculation of bacteria and, c) gout patients are more likely to have arthrocentesis or intraarticular steroid injection which may also contribute to the risk of septic arthritis. (Lim et al, 2015) It is recommended that synovial Gram stain and culture are sent even when urate crystals are identified in synovial fluid (Yu et al, 2003). In pseudogout synovial crystals of pyrophosphate dihydrate are poorly visualized by plain light microscopy but compensated polarized light microscopy may permit recognition of their weak positive birefringence. They are though less readily identified and often less numerous than urate crystals and may be missed. Chondrocalcinosis and calcification may be visible on standard radiography but their presence is not a prerequisite for a diagnosis of pseudogout.

Clinical epidemiology – critical appraisal of evidence

George Peat, Ian Scott, Weiya Zhang

A previous version was co-authored by Michelle Hui, Daniel Aletaha, Weiya Zhang, Philippe Ravaud, David Torgerson, Candice Estellat

LEARNING OUTCOMES

- Identify major bias in randomised controlled trials
- Interpret estimation of treatment effect and its precision
- Explain the concept of p value and confidence interval
- Apply therapeutic evaluation results in clinical practice
- Explain the caveats of translating evidence into practice
- Identify major bias in studies evaluating diagnostic tests
- Interpret diagnostic test characteristics (sensitivity, specificity, predictive values, receiver operating characteristic curve, and likelihood ratio)
- Apply diagnostic accuracy results in clinical practice
- Identify major bias in meta-analysis of randomised controlled trials
- Assess heterogeneity and interpret meta-analysis results
- Apply meta-analysis results in clinical practice

1- INTRODUCTION

*“Read not to contradict or confute;
nor to believe and take for granted;
...but to weigh and consider.”*

Francis Bacon, *Of Studies* (1597)

Critically appraising a paper is important in order to be able to interpret the data appropriately and to be able to apply this evidence to practice. This chapter concentrates on the critical appraisal of randomised controlled trials (RCTs), of meta-analyses of RCTs, and of studies of diagnostic test accuracy. There are sources of guidance on aspects of critical appraisal for other types of studies (e.g. qualitative research (Giacomini et al., 2000a; Giacomini et al., 2000b), economic evaluations (Drummond et al., 2015), prognosis studies (Hayden et al, 2013), non-randomised studies of the comparative effectiveness of interventions (Sterne et al, 2016)) but these will not be covered in this module.

Irrespective of the type of study, a practical approach to critically appraising medical literature uses a common set of key questions (Guyatt and Rennie, 1993*; Guyatt et al, 1994*; Jaeschke et al, 1994a*; Jaeschke et al, 1994b*; Oxman et al, 1994*; Murad et al., 2014*; Guyatt et al, 2015*). By answering these questions the reader can obtain a solid picture about the value of the particular piece of evidence at hand.

‘What is the aim of the study?’

Usually you find the answer to this question at the end of the introduction. A clearly focused objective for studies evaluating the effects of treatment will typically mention the Population, the Intervention, the Comparator, and the Outcome (PICO). The population entails the relevant patients, the intervention delineates the management strategies of interest (i.e., drugs, medical devices, but also educational, rehabilitative, behaviour change, service re-organisation, and so on), the comparator is the alternative course of action against which the intervention is to be compared, and the outcome identifies the measure of the efficacy of the intervention (**Box 1**).

Box 1. Examples of PICO objectives for studies evaluating the effects of treatment

- The effect of monthly intravenous injections of sifalimumab versus placebo on attainment of SLE responder criteria at 52 weeks among patients with moderate-severe active SLE
- The efficacy of standardised monitoring using the DAS28 versus usual care on DMARD prescription and disease activity in rheumatoid arthritis
- The effectiveness of a multifaceted podiatry intervention in reducing falls among people aged over 65 years

Note that the PICO format may need to be adapted for other types of study. For example, a clearly focussed objective for a study evaluating the diagnostic accuracy of a new test for a disease of interest will mention the population, the test, the reference standard, and the disease of interest (see **Box 2**).

Box 2. Example of a focussed objective for a diagnostic accuracy study

- To compare the sensitivity and specificity of the CONTEST and PEST screening questionnaires against rheumatologist diagnosis in patients presenting to primary care with suspected psoriatic arthritis

‘Are the results of the study valid?’

When judging the believability or credibility of the results, you should ask ***‘are the study methods appropriate to generate valid results?’*** Furthermore, studies may be well-designed but not go according to plan. Bias may be introduced by problems with recruitment, loss to follow-up, missing data, or selective reporting. So, consider also ***‘was the design well-executed?’*** and ***‘are the results reported in a full and transparent way?’*** The source of funding may be important when looking for (hidden) threats to the study’s validity such as selective reporting of outcomes in clinical trials. Industry-sponsored trials tend to report more favourable results and conclusions than non-industry-sponsored trials and the source of this bias may be difficult to discern from the report alone (Lundh et al., 2012). If, when reading a research article, you have serious concerns about the potential for bias, or the study is simply too small to generate an estimate with an appropriate level of precision (‘under-powered’), then you may choose not to read on.

What are the results?’

Studies do not produce a simple ‘yes/no’ result. In general, they produce an estimate that has a *direction* (‘positive’, ‘negative’), a *magnitude* (‘large’, ‘small’), and an accompanying level of *precision* (typically summarised by the 95% confidence interval). Depending on the design and objective of the study, that estimate may be a relative risk, an odds ratio, a difference in means, a hazard ratio, a likelihood ratio or some other parameter. But it is important to note that when we ask the question ‘are the results of the study valid?’ what we are really focussed on is whether the estimate from the study is unbiased.

‘How can I apply these results to patient care?’

This question has two parts. First, ***‘can you generalise (apply) the results to your patient?’*** For example, one should hesitate to apply a treatment if the patient is too dissimilar from those who participated in the clinical trial. Second, ***‘if the results are generalisable to the patient, what is the net impact of implementing the drug/medical device/diagnostic technology etc?’*** For treatments, have the investigators measured all outcomes of importance to patients? The impact depends on both the benefits and risks (side effects and toxic effects) of intervention and the consequences of withholding the intervention. For other types of study (e.g.

diagnostic test accuracy) there may be no good evidence available on the impact of introducing the new diagnostic test into routine practice.

This common set of key questions provides a general approach to clinical evidence presented in the literature. In the following, we will look at specifics of three different study types, which are often used in clinical practice: intervention studies, diagnostic studies, and meta-analyses.

2- RANDOMISED CONTROLLED TRIALS

To evaluate the efficacy of a treatment the best choice is to compare two (or more) groups: one group undergoing the treatment of interest, and one (or more) not (control group).

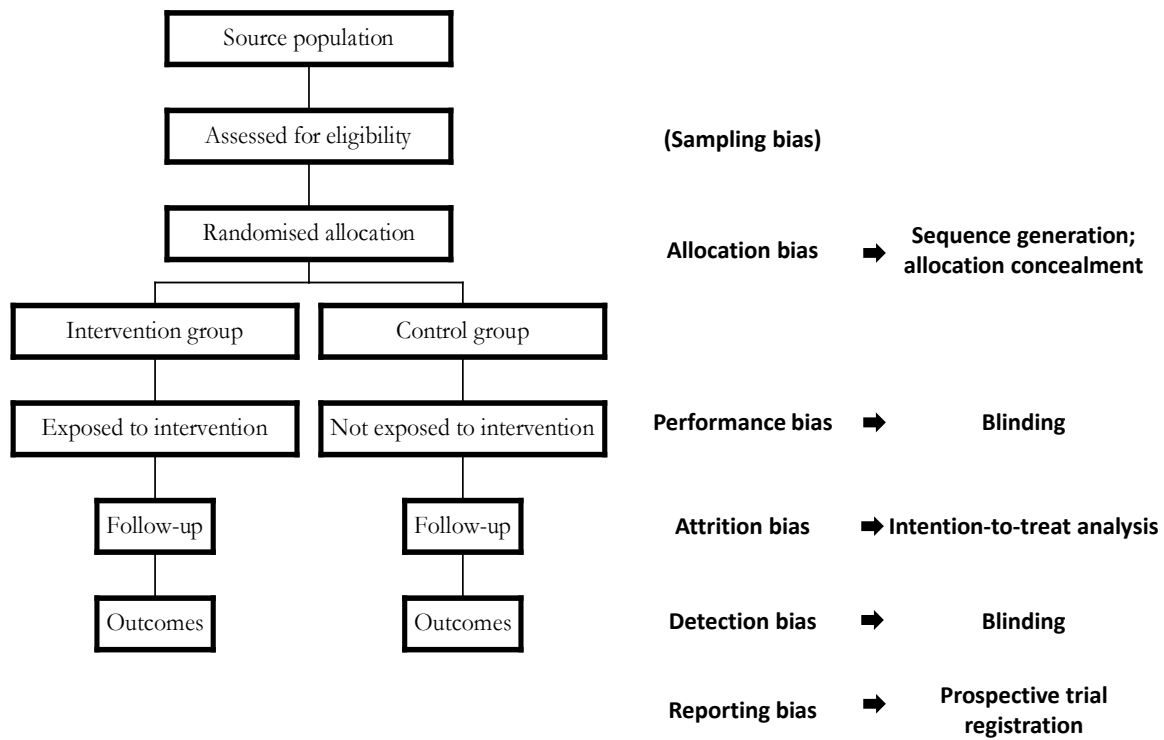

However, many factors other than the treatment under evaluation could influence patient recovery or improvement. These include the natural history of a disease, patient characteristics, special (study-related) attention paid to the patient (Hawthorne effect), regression to the mean, placebo effect, concomitant treatments, or measurement error.

The potential of these factors to bias the estimate of treatment effect is minimised if:

- Patients in each group are similar at the beginning of the study (at baseline); they have the same natural history of the disease under investigation, and show the same demographic and clinical characteristics
- This similarity between patient groups is maintained throughout the study: the same attention is paid to patients in each group, and there are no differences in access to or use of concomitant treatments
- Outcomes are measured using the same methods in each group

Systematic bias is defined as anything that erroneously influences the conclusions about groups and distorts comparisons. Readers will encounter descriptions of many forms of bias in the medical literature, sometimes using inconsistent terminology. Some of the main sources of bias in RCTs and methods to overcome them are summarised in **figure 1**. Definitions and examples are provided in **Box 3**. These issues are discussed in more detail in the following sections.

Figure 1 Sources of bias in randomised controlled trials and methods to overcome them. (Adapted from Greenhalgh, BMJ 1997;315:305–8.)

Box 3. Definitions and examples of different sources of bias in RCTs

Sampling bias	<p>Systematic differences in characteristics between patients enrolled in the trial and those in the source population</p> <p>Patients who were enrolled into a RCT of diclofenac vs paracetamol for knee OA were younger (median age: 60 years, range 44-79) than the age distribution for all patients who attended the investigator sites and met the eligibility criteria (median age: 68 years, range 42-97).</p>
Allocation bias	<p>Systematic differences in baseline characteristics between Intervention and Control groups</p> <p>At the end of recruitment to a RCT of CBT versus simple advice and information for low back pain, 77 patients had been allocated to CBT but only 67 had been allocated to control. The groups differed in terms of baseline pain and depression scores. Investigators had allocated patients to groups on the basis of the last digit of their date of birth.</p>
Performance bias	<p>Systematic differences in care/attention received (other than intervention) between Intervention and Control groups</p> <p>In a placebo-controlled trial of the effect of long-term menopausal hormone therapy on cardiovascular outcomes, both arms had an equal (and low) proportion of participants using statins at baseline. However, in the following years the rate of initiating statins was significantly higher in the placebo arm (Manson et al., 2016).</p>
Attrition bias	<p>Systematic differences in study withdrawals and loss to follow-up between Intervention and Control groups</p> <p>In a trial of hip protectors for prevention of fall-related hip fracture, 26% of participants randomised to intervention or control did not complete questionnaires at 12-months. This attrition was higher in the control arm than in the intervention arm (28% vs 22%). Although baseline characteristics had been well-balanced by the original randomisation, when the comparison was then limited to those who were successfully followed up at 12 months, patients in the control arm were less likely than those in the intervention arm to have had a previous fracture at baseline (Birks et al., 2004; Dumville et al., 2006).</p>
Detection bias	<p>Systematic differences in outcome assessment between Intervention and Control groups</p> <p>In an open-label RCT of honey-impregnated wound dressings versus usual care for venous ulcers, investigators found a small, statistically significant benefit on ulcer healing at 12 weeks when evaluated by a nurse who was not blinded to treatment allocation. However, no benefit was seen when the outcome measure was ulcer healing judged from before-after photographs by an independent expert blinded to treatment allocation.</p>
Reporting bias	<p>Selective reporting of outcomes</p> <p>In an RCT investigators recorded a few more serious adverse events among participants randomised to the active treatment arm. But they couldn't be easily explained clinically, only a small number of participants were affected, and the trial was underpowered to detect any statistically significant between-arm differences in harms. In the interests of brevity and simplicity, the investigators decided to omit them from the paper.</p>

2-1 Are the Results of the Study Valid?

2-1-1 Randomisation

Randomisation, the random allocation of patients to intervention or control groups, is the best way of minimising systematic differences between groups at baseline in characteristics, known and unknown, that may affect the outcome. Proper randomisation rests on two equally important elements to ensure that participants are assigned to groups on the basis of a chance (random) process characterised by unpredictability: (1) sequence generation, and (2) allocation concealment.

Adequate generation of the sequence usually involves a random-number table or a computerised random-number generator. Deterministic allocation methods (sometimes called 'quasi-random' methods), such as alternation, date of birth or first letter of name, are inadequate for two reasons: first, their predictability, which allows for the scheduling of participants, and second, the possible correlation between the item used (month of birth, first letter of name, etc) and the outcome.

When implementing the sequence of randomisation, if the allocation is not concealed before the patient is assigned to a group, all benefits of randomisation are lost. Investigators or clinicians can schedule patients so that those with particular characteristics receive a certain allocation, thereby biasing the allocation. A review assessing the quality of reports of RCTs in rheumatology published between 1997 and 1998 found the method of allocation concealment described in only 19% of reports (Hill et al, 2002). More recently Nüesch et al (2009) found 46 of 158 (29%) osteoarthritis trials had adequate allocation concealment. While allocation bias can work in the either direction (Paludan-Müller et al, 2016), inadequate/unclear sequence generation and allocation concealment tend to result in exaggerated estimates of treatment effects, particularly when the outcome measure is subjective (Page et al, 2016).

Allocation concealment is generally assured when treatment and placebo are indistinguishable (same appearance, same schedule of administration, same taste, etc) the care provider and the patient are blind. In other cases, the following are some approaches that assure adequate concealment schemes:

- Pre-numbered or coded identical sealed, opaque envelopes administered serially to participants
- Centralised (e.g., after patient consent is obtained, the investigator calls a 24-hour free phone service to obtain the patient allocation group) or pharmacy-controlled randomisation
- On-site computer system combined with group assignments in a locked unreadable computer file that can be assessed only after entering characteristics of an enrolled participant.

Sealed opaque envelopes have been used for randomisation for a long time. However, this process is open to deliberate tampering because the investigator can open several envelopes beforehand and then allocate

patients to the desired treatment. Indeed, sometimes treatment allocation can be seen if the envelope is held against a very bright light (Torgerson and Roberts, 1999).

It can readily be appreciated that randomisation prevents “confounding by indication” which presents nearly insurmountable problems for observational studies seeking to compare the intended effects of treatments based on patterns of use in routine practice. In routine practice, treatment allocation is guided by prognosis and not at random: patients receiving one treatment can seldom be assumed to have the same baseline risk of outcome as those not receiving that treatment.

Important demographic and clinical characteristics for each study group should be described so that readers can assess how comparable the groups were at baseline for the known prognosis factors. It is generally not useful to test these differences statistically, as by the virtue of randomisation, all observed differences must be ‘by chance’. It should rather be the magnitude and direction of the differences that may detect potential subversion of the randomisation. If several differences were large and all favoured one group our index of suspicion about the trial would be heightened.

2-1-2 Blinding

Similarity between the treatment and the control groups, except for the specific treatment condition, must be maintained during the study. Blinding is the best way to maintain this similarity and thus avoids performance bias and detection bias. Blinding refers to keeping people who are involved in the trial, such as participants, healthcare providers (i.e., those administering the treatment), and those assessing the trial outcomes, unaware of the treatment being administered.

Although the term ‘double blind’ implies that neither the care provider nor the patient knows which treatment was received, it is ambiguous with regard to blinding of other people, including those assessing patient outcomes (Montori et al, 2002). Authors should state, and readers should carefully assess, who was blinded (participants, care providers, outcome assessors, monitors, or data analysts).

Blinding of participants and healthcare providers prevents performance bias. This bias may occur if additional therapeutic interventions (i.e., co-interventions) are provided preferentially in one of the comparison groups. It guarantees the same follow-up, the same attention to the patient, and the same ‘placebo effect’ in the two groups.

Blinding of outcome assessors minimises the risk of detection bias. This type of bias occurs if treatment group influences the process of outcome assessment—for example, non-blinded neurologists assessing the outcome of a trial demonstrated an apparent treatment benefit, whereas blinded neurologists did not (Noseworthy et al, 1994). Blinding of outcome assessors is particularly important for subjective outcomes (e.g., pain scores or stiffness), which present great opportunities for bias in measurement. In general, blinding becomes less

important in reducing detection bias as the outcome becomes less subjective. Objective (hard) outcomes leave little opportunity for detection bias. Knowledge of the intervention would not greatly affect measurement of a hard outcome such as death (Schulz and Grimes, 2002), although it might influence subjective assessment such as cause of death. Note that although clinicians and patients cannot be blinded in some trials (e.g., surgery), assessors can usually be blinded.

Blinding of data analysts can also prevent bias because knowledge of the intervention received may influence the choice of analytical strategies and methods. When the two treatments under study are indistinguishable (same characteristics, same schedule of administration, same dosage, etc), blinding of patients, care providers and outcome assessors is easy to achieve (Boutron et al, 2006*). If treatments differ, a 'double-dummy' procedure may be useful but not always feasible. In a double-dummy procedure, the patients of group A receive the drug A and a placebo of drug B, and patients of group B receive the drug B and a placebo of drug A. A typical example would be the comparison of an intravenous drug to an oral drug.

When blinding of patients and care providers is not feasible (e.g., surgery, regimen, rehabilitation or psychotherapy), performance bias may occur. Sometimes blinding seems feasible but cannot be effective: because of the specificity of adverse effects, such as bradycardia with β -blockers, patients and/or care providers will quickly become un-blinded to the treatment. In these situations, methods to blind outcome assessors are particularly useful to avoid detection bias (Boutron et al, 2006*). These methods rely mainly on a centralised assessment of the main outcome. Although centralised assessment is easy to implement for investigations (e.g., laboratory tests or radiography) or clinical events (blinded adjudication committee), it requires more inventive solutions for physician-driven data (such as videotaping, audiotaping or photography of clinical examination) (Boutron et al, 2006*). For patient-reported outcomes, centralised assessment is of course much more problematic.

2-1-3 Analysis approach

Even if a rigorous trial has been undertaken and has avoided all the biases, an incorrect analytical approach can introduce bias. In a randomised superiority trial the most robust analytical method that prevents attrition bias is the intention-to-treat (ITT) analysis (Hollis and Campbell, 1999).

The advantages of an ITT analysis are balance in prognostic factors arising from the original random treatment allocation, an unbiased estimate of treatment effect, and the admission of non-compliance and protocol deviations, which thus reflects a real clinical situation (Heritier et al, 2003). Even if a patient crosses over from one treatment to another he has to be analysed in the group to which he was initially randomised. An ITT analysis answers the question 'Which choice of treatment is better for the patient?', not 'Which treatment received is better for the patient?'. The former is the only question that can be answered without bias and it is the most pragmatic one to choose a treatment.

Box 4. Analysis approaches in RCTs

intention-to-treat (ITT) analysis	all patients are analysed in the group to which they were initially randomised, even if they 'cross over' into the other intervention arm, stop their intervention, or are lost to follow-up
per-protocol (on-treatment) analysis	analysis is restricted to participants who fulfil the protocol in terms of eligibility, interventions (treatment received), and outcome assessment
treatment-received analysis	patients are analysed according to the treatment they actually received, regardless of the treatment they were originally allocated to receive

Many authors claim they perform an ITT analysis when in fact they do not. Circumstances where a true ITT analysis is not performed include:

- patients who are excluded from the analysis if they do not receive treatment
- ineligible patients who are randomised
- exclusion of patients lost to follow-up or for whom the outcome was not assessed.

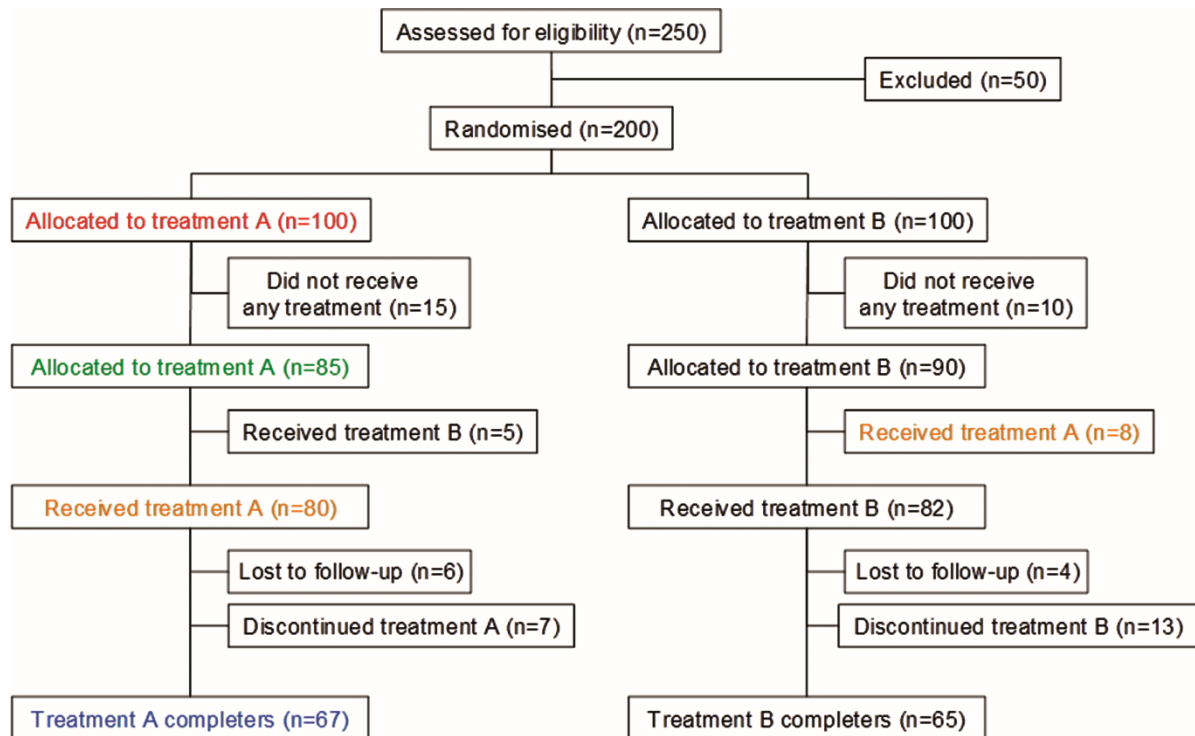

Check the ITT assumption by looking at the flow chart of the progress of patients through the phases of the trial and comparing the number of patients randomised to the number analysed (**figure 2**). Analysis excluding patients who never received any treatment is usually called “modified-” or “quasi-ITT” analysis.

The only acceptable exclusions from an analysis are patients in a strictly double-blinded study who did not receive any treatment. As patients do not know the treatment they will receive, their exclusions are unlikely to be caused by a disillusion in the allocation. If the attrition rate is low and is equally distributed between the study arms, the analysis is unlikely to be too biased. The rule of thumb for attrition is as follows: if it is less than 5%, it is unlikely to have introduced bias; if it is greater than 20% (particularly if it is unequal between groups), then there is a real risk of bias; if it is between 5% and 20%, we need to be cautious and look for sensitivity analyses of the data.

Non-compliance with assigned therapy means that the ITT analysis may underestimate the real benefit of the treatment; it is a conservative analysis. Additional analyses such as per protocol or treatment-received analysis may therefore be considered, but only to generate more research hypotheses not used to inform the treatment decision (see box 4). In particular, because ITT analysis may underestimate effects, it is not appropriate for examining adverse effects or equivalency trials. An alternative analytical approach, which in theory does not affect the randomisation, is to use a complier average causal effect (CACE) analysis. This

approach, if certain assumptions are fulfilled, produces an estimated effect of treatment taking into account non-compliance (Hewitt et al, 2006).

Figure 2 Flow chart of participants through each stage of a randomised controlled trial. (Adapted from Moher et al, JAMA 2001;285:1987–91.)

Patients included in each type of analysis of treatment A effect :

Intention-to-treat analysis
 Modified Intention-to-treat analysis
 Per-protocol analysis
 Treatment received analysis

If a large proportion of patients cross over to opposite treatment arms or are lost to follow-up, the interpretation of study results will be difficult, and neither an ITT nor a per-protocol analysis provides reliable information. An extreme example is the Spine Patient Outcomes Research Trial (SPORT), which compared standard open discectomy versus non-operative treatment for patients with lumbar intervertebral disk herniation. Only 60% of patients assigned to surgery received surgery, as compared with 45% of those assigned to non-operative treatment (Weinstein et al, 2006). Whatever the analysis performed, none will be informative.

The reality of conducting clinical trials means that the ITT principle is not usually fully met, especially when outcome data are missing. Therefore, performing an ITT analysis usually implies choosing a method to handle missing data. Because missing data may occur for various reasons, including adverse events related to the treatment, the method used for data imputation must be conservative—that is, not favour the treatment group.

One widely used method for data imputation is replacement by the last observation available for the patient (last observation carried forward (LOCF)), but the assumptions needed for this to produce a valid estimate are seldom met. LOCF should be viewed with suspicion in favour of preferred methods, including multiple imputation and mixed effects models (Bell et al, 2014) and sensitivity analyses (i.e., analysis evaluating the influence of different methods of handling missing data). An example of a simple sensitivity analysis is provided in **Box 5**.

Box 5. Example of simple sensitivity analysis

Kontiokari et al (2001) undertook an RCT of cranberry juice to prevent recurrent urinary tract infections (UTIs) among women. They found a significant benefit of the treatment; however, 8% of the cranberry group and 10% of the control group were lost to follow-up. The authors checked their data by assuming all of those who dropped out of the cranberry group got an infection and all of those in the control did not. The new results still showed a significant advantage for cranberry juice

2-1-4 Outcome measurement

A crucial issue in assessing trials is the actual measure of whether something works or not. The outcome chosen to conclude the effectiveness of the treatment could be either a clinical event (e.g. death, fracture), a therapeutic decision (e.g. length of stay, transfusion, surgery), a patient-reported outcome (e.g. pain, fatigue), or a biological, physiological, or morphological measurement (e.g. synovitis from MRI).

Most outcomes can be measured as a dichotomous variable (e.g. event/no event), as a continuous variable (e.g., blood pressure, glycaemia, WOMAC (Western Ontario and McMaster Universities Osteoarthritis Index) scale) or as time to the onset of an event (survival time data).

Whatever its nature, a good outcome must:

- be clinically relevant
- be unique
- be recognised in other studies
- have good reliability and reproducibility
- be available for all patients to avoid attrition bias.

Clinical relevance and surrogate outcomes

To decide whether to apply the study results, one needs evidence that treatment improves outcomes that are important to patients. Having an elevated blood pressure is of little interest to the patient, whereas having a stroke is of major importance.

A good outcome must be clinically relevant for the patient; examples include death, length of hospital stay, myocardial infarction, fractures, and quality of life. The length of follow-up has to be consistent with disease evolution. For example, a follow-up of only 1 month is unlikely to be appropriate for chronic disease outcomes. Kyriakidi and Ioannidis (2002) showed that only 11% of RCTs of systemic sclerosis had a follow-up of more than 1 year.

However, usually these outcomes are substituted by 'surrogate' outcomes, generally biological or imaging markers, which are easier to measure and believed to be indirect measures of the clinically relevant outcome. For example, change in bone mineral density is often used as a surrogate to measure the effectiveness of treatments for the prevention of osteoporotic fractures. As well as being of questionable clinical relevance, surrogate outcomes are often misleading (Fleming and DeMets, 1996). For example, Riggs et al (1990) found that sodium fluoride substantially increased bone mineral density but did not prevent fractures.

Surrogate outcomes are widely used because observing a difference in a surrogate measure requires a much smaller sample size and shorter follow-up as compared with a clinical outcome. Trials designed to observe changes in bone mineral density require only a few hundred participants, whereas those designed to observe a fracture endpoint require many thousands of participants. Surrogate outcomes, however, are useful in helping to guide research at its earliest stages.

Many diseases have a plethora of possible outcomes that can be measured by different scales or instruments. This may make interpretation and comparison of different studies very complex. For example, before concerted efforts to standardise outcome measurement in rheumatology RCTs, Gotzsche et al (1989) found more than 70 outcomes used in 196 RCTs of NSAIDs for rheumatoid arthritis. Where available and appropriate, consensus guidelines for core outcome sets – see, for example, OMERACT (<http://www.omeract.org/>) and COMET (<http://www.comet-initiative.org/>) – and previously developed and validated scales should be used, as this will enhance quality of measurement and assist in comparison with similar studies. Examples can be found at. Authors should indicate the origin and properties of scales. Readers should be sceptical of studies involving unconventional outcomes.

The primary outcome

A single primary outcome must be defined a priori. The study must be designed and the sample size calculated to demonstrate whether the treatment has an effect or not on this primary outcome. When outcomes are assessed at several time points after randomisation, the pre-specified time point of primary interest must also be defined a priori. These decisions may help avoid a multiplicity of statistical tests, some of which by chance alone, will be statistically significant.

The α level is the chance taken by researchers to make a type I error: incorrectly declaring a difference, effect or relationship to be true because of only chance producing the observed state of events. Customarily, the α level is set at 0.05—that is, in no more than one in 20 statistical tests the test will show some effect when in fact there is no effect. If more than one statistical test is used, the chance increases of finding at least one test result in the whole experiment that is statistically significant only due to chance and to incorrectly declare a difference or relationship to be true. In five tests this chance equals 0.22, or 1 in 5; in 10 tests, this chance increases to 0.40, or about 1 in 2. There remains a debate on whether and how far to extend the principle of correction for multiple testing, e.g. in multi-arm trials (Wason et al., 2014).

Other outcomes of interest are secondary outcomes. There may be several secondary outcomes, and these should also be pre-specified and fully reported (not just those showing a statistically significant difference). Important outcomes must be considered, but a single study must not have too many outcomes. Adverse events and reactions are important but often poorly handled secondary outcomes.

Many trials recruit participants over a long period. If an intervention is working particularly well or badly, the study may need to be ended early for ethical reasons. Interim analysis could be performed. However, as explained above, performing repeated multiple statistical examinations without appropriate correction can lead to erroneous results and interpretations. The overall study results are not biased if interim analysis is planned in advance, statistical methods adapted, and results of analysis are interpreted by an independent committee which may decide to stop, or not stop, the study.

Composite outcomes

With no obvious choice of primary outcome in a trial, trialists can adopt the composite of several outcomes. An example of a composite outcome to evaluate the efficacy of a new stent could be the occurrence of one of the following events: death, reinfarction, stroke, or repeat target vessel revascularisation.

The advantages of this option could be to avoid the need for arbitrary choices in deciding which outcome to elect as the primary one and to increase the power of a study for the same number of patients included (as more events are supposed to occur, and the composite more robustly and accurately represents the outcome of interest). This solution helps deal with the issue of multiplicity of tests. However, a major disadvantage lies in the interpretation of results. Composite outcomes sometime combine events of very different severity, and the treatment effect can be driven by the least important outcome, which is often the most frequent. When interpreting results it is important to bear in mind that the effect described relates to the entire composite outcome and not to each component of the outcome.

Freemantle et al (2003) proposed five recommendations on the appropriate use of composite outcomes:

- Trialists should follow the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Moher et al, 2010*) and identify precisely the pre-specified primary and secondary outcome measures, reporting the results clearly in publications that describe the trial.
- When trials report composite variables as primary outcomes, these should be interpreted together rather than as demonstrating efficacy of individual components of the composite.
- Components of composite outcomes should always be defined as secondary outcomes and reported alongside the results of the primary analysis, preferably in a table.
- Authors and journal editors should ensure that the reporting of composite outcomes is clear and avoids the suggestion that individual components of the composite have been demonstrated to be effective.
- Systematic overviews and quantitative meta-analyses should be used to identify the effects of treatments on rare but important endpoints that may be included as part of composite outcomes in individual trials.

Reliability and reproducibility

Some outcomes are easier to measure than others. Death (from any cause) is usually easy to assess, whereas joint-space narrowing or quality of life are more difficult to measure. Some strategies can be used to improve the quality of measurements. For example, assessment of joint-space narrowing is more reliable if performed by two independent trained observers and if technical acquisition of radiography is standardised. A measure of reproducibility, corrected for agreement by chance, such as the kappa (κ) coefficient, helps in assessing the quality of the measure.

Independence

Standard methods of analysis assume that the data are 'independent'. For RCTs, this usually means that each comparison test involves only one observation per participant. Treating multiple observations from one participant as independent data is a serious error; such data arise when outcomes can be measured at successive times or from different parts of the body. For example, in a trial of osteoporosis, treating two vertebral fractures in the same patient as two independent observations is incorrect. The correct approach is to count the number of patients with at least one vertebral fracture. Data analysis should be based on counting each participant once (Altman and Bland, 1997; Bolton, 1998) or should involve specific statistical procedures taking into account the clustered or multi-level nature of the data (i.e. fractures within patients). An analysis of 196 trials in rheumatoid arthritis (Gotzsche, 1989) found that 63% of trials used multiple observations.

2-1-5 Subgroup analysis

Multiple analyses of the same data incur considerable risk for false-positive findings. As previously discussed, this risk should lead to a limitation on the number of outcomes and the number of occasions on which they are assessed. The same risk imposes that multiple analyses of the same outcome in different subgroups of patients must be avoided.

Because of the high risk for spurious findings, subgroup analyses do not have great credibility. When considering results of a subgroup analysis, remember the following (Rothwell, 2005b; Sun et al., 2014*):

- Subgroup analysis should be defined before starting the trial and should be limited to a small number of clinically important questions.
- If important subgroup-treatment effect interactions are anticipated, trials should ideally be powered to detect them reliably.
- Significance of the effect of treatment in individual subgroups should not be reported; rates of false-negative and false-positive results are extremely high. The only reliable statistical approach is to test for a subgroup-treatment effect interaction, but few trials are powered to detect this.
- All subgroup analyses that were done should be reported.
- Until their findings are reproduced in other trials, subgroup analyses must be regarded as hypothesis-generating, and not as hypothesis testing.

2-3 What are the Results?

If the results are valid and the study likely yields an unbiased assessment of treatment effect, then the results are worth examining further.

First, for each outcome, study results should report a summary of the outcome in each group (e.g. the proportion of participants with the event, or the mean and standard deviation (SD) of measurements) (Guyatt et al, 1994*).

Then, to appreciate the treatment effect, two additional data must be reported:

- the contrast between the two groups, known as the measure of treatment effect, and
- an estimation of the precision of this measure, the statistical significance of the treatment effect (confidence interval (CI) and/or p value).

2-3-1 Measures of effect size

Readers of randomised clinical trials can expect to encounter several different summary measures of treatment effect. The more common ones are shown in **Box 6**.

Box 6. Some common summary measures of treatment effect used in RCTs

<i>Level of measurement</i>	<i>Example</i>	<i>Summary measure of treatment effect</i>
Dichotomous	Proportion of patients dead at follow-up	Risk difference (RD) (also known as absolute risk reduction (ARR)) Risk ratio (also known as relative risk) (RR) Relative risk reduction (RRR)
Time-to-event	Time to first hip fracture	Hazard ratio (HR) Difference in mean/median survival time
Continuous	Percentage change in femoral neck bone mineral density	Difference in means

Dichotomous outcomes

Consider the simple trial finding in **Box 7**.

Box 7. An example of a RCT with a dichotomous outcome

	Treatment group	Control group
Proportion of participants dead at 12 month follow-up	15%	20%

How might these results be expressed?

One way would be as the absolute difference (known as the risk difference (RD) or absolute risk reduction (ARR)) between the proportion dying in the control group (x) and the proportion dying in the treatment group (y):

$$ARR = x - y = 0.20 - 0.15 = 0.05 = 5\%.$$

Another way would be as a relative risk (RR): the risk of events among patients having the new treatment relative to the risk among patients in the control group:

$$RR = y/x = 0.15 / 0.20 = 0.75 = 75\%$$

The most commonly reported measure of dichotomous treatment effects is the complement of the relative risk, the relative risk reduction (RRR), which is expressed as a percentage:

$$RRR = (1 - RR) \times 100 = (1 - 0.75) \times 100 = 25\%$$

or

$$RRR = ARR/x = (0.20 - 0.15)/0.20 = 25\%$$

A RRR of 25% means that the new treatment reduced the risk of death in the treatment group by 25% as compared with the control group; the greater the RRR, the more effective the treatment. Investigators may compute the RR over a period of time, as in a survival analysis, and call it a hazard ratio. When authors do not specify whether they are talking about RRR or ARR—for example, ‘Drug X was 30% effective in reducing the risk of death,’ or ‘The efficacy of the vaccine was 92%’—they are almost invariably talking about RRR.

For some treatments and conditions, the benefit of a specific treatment, as measured by the RR or RRR, remains approximately constant over patient populations at various baseline risks (Cook and Sackett, 1995). Since a single estimate of treatment effect can be provided for a broad class of patients, RR and RRR appear attractive. However, it is often clinically important to consider the baseline (control) risk of an event before recommending treatment, because for a given RRR, the expected absolute benefit of treatment could vary considerably as the baseline risk changes. For example, an estimated RRR of 50% might be important for patients at moderate to high risk for a particular adverse event. However, for patients with a low probability of an event, the risk reduction might not be sufficient to warrant the toxic effects and cost of treatment (Cook and Sackett, 1995).

Because RRR or RR fails to discriminate between enormous and very small effects in absolute number, the ARR is considered a better measure of treatment effect. However, the ARR is usually expressed as a decimal fraction (e.g., 0.06, 0.14, etc) which is difficult to interpret in clinical practice. The reciprocal of ARR, the number needed to treat (NNT), is therefore recommended (Osiri et al, 2003):

$$\text{NNT} = 1/\text{ARR}$$

The NNT is the number of patients who would need to be treated with the new treatment rather than the control for one additional patient to benefit (Laupacis et al, 1988). It can be obtained for any trial that has reported a dichotomous outcome.

In the example above, the ARR between the proportions in the control and treatment groups who died is 0.05, so the NNT would be $1/0.05 = 20$ —that is, 20 patients would need to be treated in order to prevent one additional death.

A large treatment effect, in the absolute scale, leads to a small NNT. A treatment that leads to one saved life for every 10 patients treated is clearly better than a competing treatment that saves one life for every 50 treated.

The ideal NNT is 1, whereby everyone has improved with treatment and no one has improved with the control. The higher the NNT, the less effective the treatment. However, the value of an NNT is not just numeric. For example, NNTs of 2–5 are indicative of effective therapies such as analgesics for acute pain, NNTs of

approximately 1 might be achieved by treating sensitive bacterial infections with antibiotics, whereas an NNT of 40 or more might be useful in the use of aspirin after a heart attack.

A correctly specified NNT must always give the comparator, the therapeutic outcome, the duration of treatment necessary to achieve that outcome, the 95% CI and the baseline risk of event without treatment.

While NNT estimates the benefit of a treatment, the number needed to harm (NNH) may estimate the potential risk of the treatment. Its calculation is similar to the NNT:

$$NNH = 1/(\text{proportion of adverse events in the treatment group} - \text{proportion of adverse events in the control group})$$

Comparison of NNT and NNH, by weighing benefits and risks, helps to evaluate the benefit/risk ratio of a treatment.

The NNT reflects the fact that the effect of a treatment for a patient is related not only to its RRR but also to its baseline risk. For a given treatment, RRR is the same for all patients, but NNT varies with the individual patient baseline risk. The higher the probability that a patient will experience an adverse outcome with no treatment, the more likely the patient will benefit from treatment and the fewer patients need to be treated to prevent one adverse outcome. Box 8 provides an illustrative example.

Box 8. Example of weighing benefits and harms in patients with different baseline risks of each

Results of clinical trials suggest that hormone replacement therapy reduces the relative risk of spine fracture over a lifetime by approximately 30%, but such therapy also increases the risk of stroke by 50%. Consider two menopausal women with different baseline expected rates of spine fracture and stroke: patient A has low bone mineral density but no cardiovascular risk factors; patient B has normal bone mineral density but many cardiovascular risk factors. The table below summarises the NNT and NNH values for these two women to help in clinical decision making by balancing the risks and benefits in each case.

		Risk without HRT	Risk with HRT	Relative risk variation (reduction or increase)	Absolute risk variation (reduction or increase)	NNT or NNH
Patient A	Spine fracture	0.20	0.14	0.30	0.06	17
	Stroke	0.01	0.015	0.50	0.005	200
Patient B	Spine fracture	0.10	0.07	0.30	0.03	33
	Stroke	0.03	0.045	0.50	0.015	67

Treating approximately 200 women like patient A will prevent 12 spine fractures ($200 \times 1/17$) but induce one stroke. Given the small increased risk of stroke and the number of spine fractures prevented, many clinicians might suggest hormone replacement therapy for such patients.

However, treating approximately 200 women like patient B will prevent only six spine fractures ($200 \times 1/33$), but will induce three strokes ($200 \times 1/67$). Obviously, hormone replacement therapy is less indicated in these patients.

HRT Hormone replacement therapy; NNT Number needed to treat ; NNH Number needed to harm

Continuous outcomes

For continuous outcomes, the measure of treatment effect is the difference in means between the treatment and control group. The standard deviation (SD) reflects the dispersion of values around the mean.

Results of continuous outcomes are usually difficult for clinicians to use in clinical practice because of problems in assessing their clinical importance or in comparing benefits with risks across various therapeutic options.

Comparing the effect of treatment among studies involves the effect size (d): the difference between two means (treatment minus control group) divided by the pooled SD of the two groups – equivalent to the number of SDs between the two means:

$$d = (\text{Mean}_t - \text{Mean}_c) / \text{SD}_{\text{pooled}}$$

$$\text{with } \text{SD}_{\text{pooled}} = \sqrt{\frac{(n_t - 1)SD_t^2 + (n_c - 1)SD_c^2}{n_t + n_c}}$$

and where: *t* refers to treatment group, *c* refers to the control group, and *n* is the number of subjects. Box 9 provides an illustrative example.

Box 9. Estimating effect size from continuous outcomes: a worked example

	Treatment group (n=98)	Control group (n=96)
Mean (SD) HAQ score at 3 months	6.0 (2.5)	5.3 (2.1)

$$\text{SD}_{\text{pooled}} = \sqrt{\frac{(98 - 1)2.5^2 + (96 - 1)2.1^2}{98 + 96}} = 2.3$$

The effect size (d) = $(\text{Mean}_t - \text{Mean}_c) / \text{SD}_{\text{pooled}} = (6 - 5.3) / 2.3 = 0.3$

The division by the SD allows for comparison of effect sizes across studies.

Opinions vary on how to interpret effect size, but the most accepted advice is by Cohen (1992), for whom 0.2 is indicative of a small effect, 0.5 a medium effect, and 0.8 a large effect size.

HAQ Health Assessment Questionnaire

Translating a continuous measure (e.g., HAQ) to a dichotomous measure such as ‘therapeutic success (yes/no)’ usually leads to more clinically meaningful results. This dichotomisation may help in interpreting and assessing the clinical significance of trial results. It allows for an NNT calculation that is usually more meaningful than the difference in means. It is more meaningful to say ‘one needs to treat five patients for halving the EVA score in one patient’ than ‘difference in EVA score between treatment and placebo is 9.7 mm (SD = 3.7)’.

However, dichotomising a continuous variable can result in loss of information and statistical power.

A relevant cut-off value is specific to each outcome. For a patient-reported outcome such as the minimal clinically important improvement, which is the smallest change in measurement that signifies an important difference or improvement in symptoms, or the patient acceptable symptom state, the score below which patients consider themselves well, may help to determine a clinically relevant cut-off value for the dichotomisation (Tubach et al, 2005a; Tubach et al, 2005b).

2-3-2 Measures of precision of the treatment effect

Confidence interval

Realistically, the true measure of the treatment effect can never be known. The best we have is the estimate provided by rigorous controlled trials, and the best estimate of the true treatment effect is that observed in the trial. This estimate is called a point estimate, a single value calculated from observations of the sample that is used to estimate a population value or parameter. The point estimate reminds us that, although the true value lies somewhere in its neighbourhood, it is unlikely to be precisely correct. We usually (though arbitrarily) use the 95% CI to estimate the neighbourhood within which the true effect likely lies. One can consider the 95% CI as defining the range that includes the true value of the effect 95% of the time.

If the CI of a ratio contains 1 (or zero for a difference), the result is compatible with no effect, and the difference is not statistically significant. Consider the examples in Box 10.

Box 10. Confidence intervals and sample size in RCTs

If a trial randomised 100 patients each to treatment and control groups, and there were 20 deaths in the control group and 15 deaths in the treatment group, the authors would calculate a point estimate for the RRR of 25%. You might guess, however, that the true RRR might be much smaller or much greater than this 25%, with a difference of only five deaths. In fact, you might surmise that the treatment might provide no benefit (an RRR of 0%) or might even do harm (a negative RRR), and you would be right. This is because the 95% CI of the RRR is –38% (i.e., patients given the new treatment might be 38% more likely to die than control patients) to 59% (i.e., patients subsequently receiving the new treatment might have a risk of dying almost 60% less than that of non-treated patients). The trial really has not helped us decide whether to offer the new treatment.

If the trial enrolled 1000 patients per group, and the same event rates were observed as before, for 200 deaths in the control group ($x = 200/1000 = 0.20$) and 150 deaths in the treatment group ($y = 150/1000 =$

0.15), again, the point estimate of the RRR is 25% ($1 - y/x = 1 - [0.15/0.20] \times 100 = 25\%$). In this larger trial, you might think that the true reduction in risk is much closer to 25% and, again, you would be right. This is because the 95% CI for the RRR for this set of results is on the positive side of zero and is 9% to 41%.

What these examples show is that the larger the sample size of a trial, the greater our confidence that the true RRR (or any other measure of efficacy) is close to what we have observed. In the second example above, the lowest plausible value for the RRR was 9% and the highest 41%. The point estimate—in this case, 25%—does not change and is the value most likely to represent the true RRR. Values beyond the upper or lower boundaries of the 95% CI are extremely unlikely to happen if a study of the same size is repeated.

95% CIs are important for continuous outcomes as well, as illustrated in **Box 11**.

Box 11. Confidence interval for a continuous outcome

In a study of respiratory muscle training for patients with chronic airflow limitation, one primary outcome measured how far patients could walk in 6 min in an enclosed corridor. In the experimental group receiving respiratory muscle training, this 6 min walk improved, from a mean of 406 metres to 416 metres (up 10 m), and in the control group, from a mean of 409 m to 429 m (up 20 m). The point estimate for improvement in the 6-min walk due to respiratory muscle training therefore was negative, –10 m (or a 10 m difference in favour of the control group). The lower boundary of the 95% CI was –26 m (i.e., the results are consistent with a difference of 26 m in favour of the control treatment) and the upper boundary was +5 m.

Even in the best of circumstances, adding 5 m to the 400 m recorded at the start of the trial would not be important to the patient, and this result effectively excludes an important benefit of respiratory muscle training as applied in this study.

2-3-3 The p value

Many journals require or strongly encourage the use of CIs. Although p values may be provided in addition to CIs, results should not be reported solely as p values (Moher et al, 2001*). Yet CIs are not always reported, so one must look at the p value of the primary outcome.

Depending on the test used, there are many ways to calculate a p value, but its meaning is always the same. The p value tells how often the results would have occurred by chance of no difference between the two groups. In other words, the p value describes the risk of a false-positive conclusion that there is a difference when, in truth, there is no difference.

The p value reflects the statistical significance of a difference but not its size. A small difference observed with a large sample is more significant statistically than the same difference observed with a small sample. Thus, a difference could be statistically significant but clinically insignificant. The p value tells us only if the observed difference is likely to be true ($p < 0.05$) or only the result of chance ($p > 0.05$)—that is, statistically not

significant. A value of $p < 0.05$ means that this result would have arisen by chance on less than one occasion in 20.

If the p value is exactly 0.05, then the lower boundary of the 95% CI for the RRR must lie exactly at zero (RR of 1), and one cannot exclude the possibility that the treatment has no effect. As the p value decreases below 0.05, the lower boundary of the 95% CI for the RRR rises above zero.

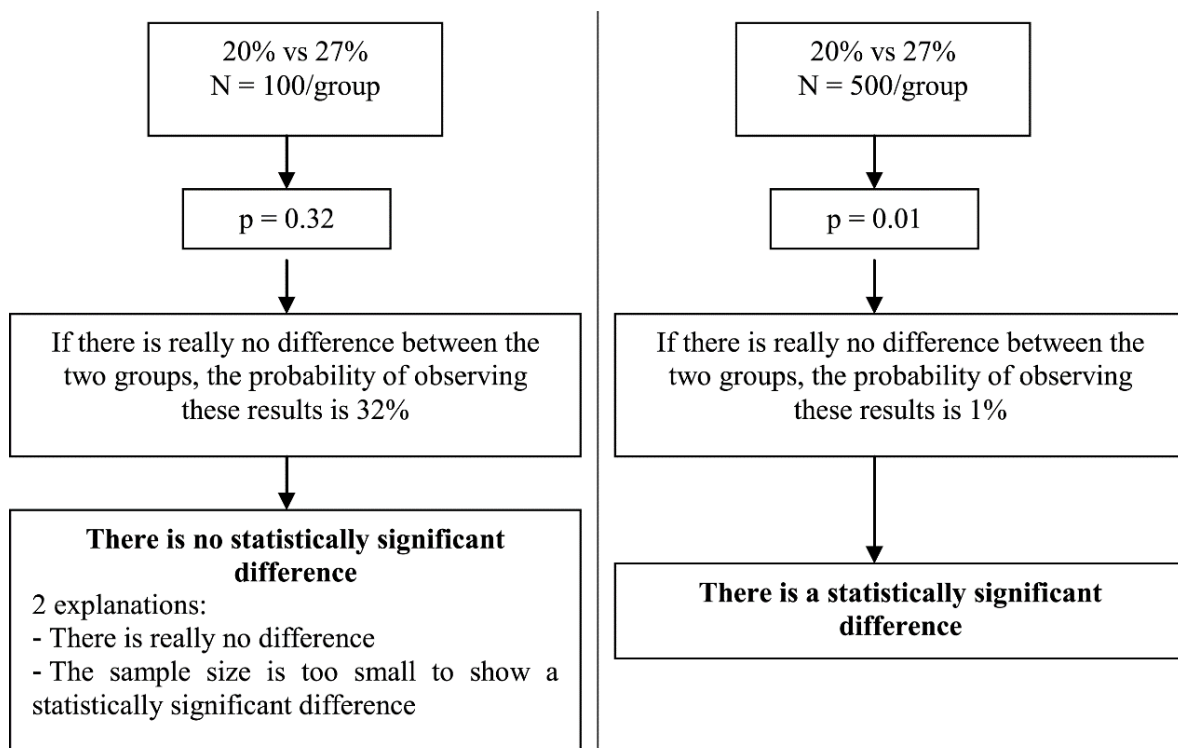

2-3-4 Clinical relevance versus statistical significance

When looking at the results of a study, one must consider two important concepts: clinical significance, and statistical significance. The former addresses the size of the treatment effect, and the latter its credibility.

The literature is full of statistically significant but clinically irrelevant results. A clinically significant finding would be one clinically useful for a patient. For example, a study may find that a certain medication causes a statistically significant ($p < 0.05$) decrease in blood pressure of 2 mm Hg, but this would not be a clinically significant decrease in blood pressure. In contrast, a study finding a statistically significant decrease in blood pressure of 20 mm Hg would be more clinically significant.

Statistical significance depends on the size of the difference between the groups, and on the number of patients. The p value alone gives no information on the magnitude of the effect. Clinically trivial differences can be statistically significant if the sample size is sufficiently large. Conversely, clinically important differences can be statistically not significant if the sample size is too small—that is, if the study lacks power (Figure 3).

Figure 3 Clinical significance and interpretation of the p value.

If the study has a positive result (the treatment group did significantly better), look at the low end of the 95% CI and determine whether this minimum treatment effect is still important or clinically significant. If so, the study results can be considered definitive. However, if one cannot consider this minimum treatment effect clinically significant, then the study cannot be considered definitive, even if its results are statistically significant (i.e., they exclude a risk reduction of 0). Remember, any difference towards the end of the CI has a low chance of being the 'true' difference, which must be taken into account.

If the study has a negative result (the treatment and control groups did about the same), there are two possible explanations: first, there is really no difference between the treatment and control groups; and second, the study did not have enough power (not enough subjects) to find a difference if there really was one. This is called a β -error, or a type II error, and the study is referred to as being underpowered. To interpret these results, look at the high end of the 95% CI and determine whether this effect would be clinically important. If so, the study failed to eliminate a potentially important treatment effect (i.e., the sample size was too small). We can conclude that, although the investigators have failed to show that the experimental treatment was better than the placebo, they also failed to show that it was not better; they have not excluded a large, positive treatment effect.

If the study report does not give a CI, another approach is to look closely at the hypothesis assumed for the sample size calculation. With a too-small sample size, even a clinically meaningful difference will never be statistically significant.

Sample size calculation for dichotomous outcomes requires four components: type I error (α), power, event rate in the control group, and a minimal treatment effect of interest (or, analogously, an event rate in the treatment group). Calculation of continuous outcomes requires, instead of event rate in the control and treatment group, difference between means and assumptions on the SD.

The sample size is probably too small if in the calculation:

- the clinically relevant minimal treatment effect assumed is too large (a smaller but still clinically relevant difference should have been chosen)
- the event rate in the control group is overestimated
- the SD is underestimated for continuous outcomes.

As an example, Keen et al (2005) found that in 50% of rheumatology reports of RCTs with negative or indeterminate results published in 2001–2002, the studies were underpowered.

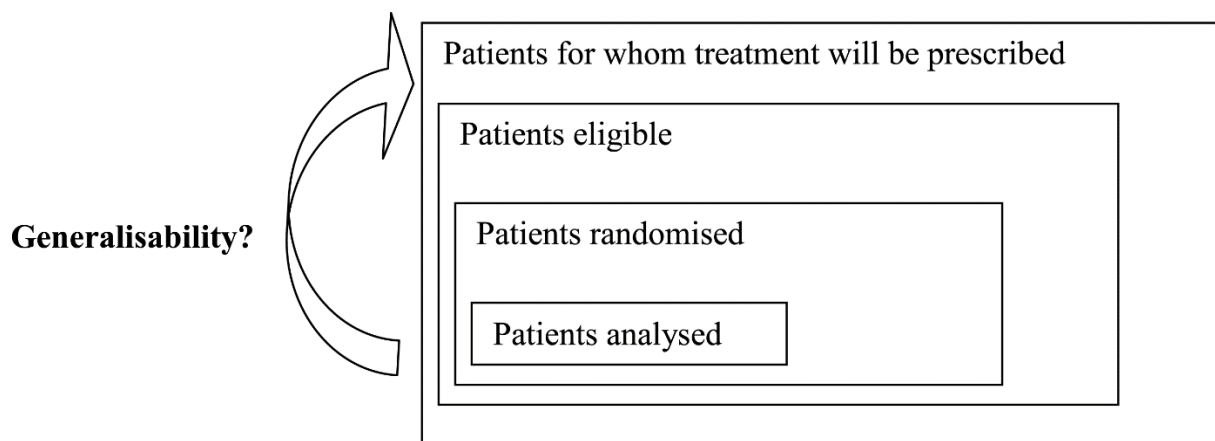

Having determined the magnitude and precision of the treatment effect, we can turn to the final question of how to apply the article's results to patients in clinical practice.

2-4 How Can I Apply These Results to Patient Care?

2-4-1 Generalisability of study results

When answering the question ‘Are the results of the study valid?’ we in fact only explored the internal validity—that is, any bias that can explain the observed effect in the subjects studied. Now we ask about the study’s external validity—that is, the generalisability of the study results (figure 4) (Guyatt et al, 1994*). Of course, if the internal validity of the study is poor, there is no point in proceeding further. If the study result is not valid even for the subjects studied, its application to other groups of subjects is irrelevant. However, if we conclude that it is a reasonably valid result, and that a causal association is a reasonably likely explanation, we need to explore the external validity of the results.

Figure 4 Differences between patients analysed and patients for whom treatment will be prescribed, raising the issue of generalisability of study results.

There is no external validity per se. The results of a study will never be relevant to all patients and all settings, but studies should be designed and reported so that clinicians can judge to whom the results can reasonably be applied.

The following criteria must be considered before applying results to patients (Rothwell, 2005a):

- **Setting of the trial:** country; healthcare system; recruitment from primary, secondary or tertiary care; selection of participating centres and clinicians.
- **Selection of patients:** eligibility and exclusion criteria, ‘run-in’ or ‘washout’ period, ‘enrichment’ strategies, ratio of randomised patients to eligible non-randomised patients.
- **Characteristics of randomised patients:** severity or stage in the natural history of disease, comorbidities, racial group, other baseline clinical characteristics.

- **Difference between trial protocol and routine practice:** relevance of control intervention, co-interventions, prohibition of certain non-trial treatments, therapeutic or diagnostic advances since the trial was performed.
- **Outcome measure and follow-up:** clinical relevance of outcomes (surrogate, complex scale, composite outcome, etc), frequency of follow-up, adequacy of the length of follow-up.
- **Adverse effect of treatment:** completeness of reporting of adverse effects, rate of discontinuation of treatment, selection of trial centres and/or clinicians on the basis of skill or experience, exclusion of patients at risk for complications, exclusion of patients who experienced adverse effects during a run-in period, intensity of trial safety procedure.

The clinical setting is never exactly the same as the trial setting and your patient often has attributes or characteristics different from those enrolled in the trial. These differences may lead to less benefit, as was shown between a phase III clinical trial and a phase IV cohort study on the use of etanercept for rheumatoid arthritis (Farahani *et al*, 2005). So one must ask whether these differences may really diminish the treatment response or increase greatly the risk of adverse events—that is, ‘Is my patient so different from the study patients that I cannot apply the results to my patient?’

2-4-2 Consideration of adverse effects

Before applying results of a study to a patient, one must consider the possible harm that any intervention might do. Regardless of this crucial information, reporting of harms in RCTs has received less attention than reporting of efficacy and is often inadequate. In 2004 an extension of the CONSORT statement focused on better reporting of harms-related data from RCTs (Ioannidis *et al*, 2004).

Looking at the rate of adverse effects (or the NNH) reported in each group helps in appraising the risks of a treatment. However, studies are never powered to detect a statistically significant difference in rates between groups. Sample sizes are usually too small for a reasonable chance of detecting an unexpected adverse effect. Therefore, some authors suggest the creation of a composite outcomes basket to be used as the primary safety outcome in clinical effectiveness trials (Tugwell *et al*, 2005).

3 DIAGNOSTIC EVIDENCE

The objective of a diagnostic test is to accurately classify patients with or without a target condition. This target condition could be a specific disorder (such as Sjögren syndrome, Behçet disease or sarcoidosis), or a specific state (such as remission, response). A diagnostic test may be a clinical symptom, a laboratory test, a morphologic exam (radiography, magnetic resonance imaging (MRI), etc) or a more invasive act such as biopsy or surgery. The result of a diagnostic test may be dichotomous, categorical or continuous (although to

facilitate decision-making a cut-off value is often selected). Although the following section deals with the simplest situation of a single diagnostic test giving a dichotomous result (positive/negative) it will be readily recognized that in clinical practice, diagnostic tests are seldom used and interpreted in isolation. Instead, any test or piece of information that may indicate the presence or absence of the target disorder suspected in a patient will be used and interpreted in the context of overall diagnostic profile of the patient.

Several different types of research study may be used to evaluate a new diagnostic test at different stages in its development:

- **Step 1: Technical performance**—is the test feasible and does it have good reproducibility?
- **Step 2: Diagnostic performance**—do the test results allow for an accurate diagnosis to be made?
- **Step 3: Diagnostic impact**—does the test change diagnostic confidence and displace other investigations?
- **Step 4: Therapeutic impact**—do the results of the test contribute to planning and delivering a therapy?
- **Step 5: Impact on health**—does the use of the test contribute to the improved health of the patient?

Randomised controlled trial designs may be best-suited to studies seeking to evaluate the impact on clinician behaviour and patient outcomes of introducing a new diagnostic test (Steps 3-5). These studies are still relatively uncommon. Instead, nearly all publications focus on the first two steps: technical and diagnostic performance (Dixon, 1997). We will focus on critical appraisal of articles reporting diagnostic performance. Further detail on critical appraisal of the validity of studies evaluating a diagnostic test is available from Jaeschke *et al*, 1994a*, Jaeschke *et al*, 1994b* or the QUADAS/QUADAS-2 checklists (Whiting *et al*, 2003; Whiting *et al*, 2011).

For establishing diagnostic performance—cross-sectional study designs are most appropriate. Investigators will typically sample patients whom they suspect may have the target condition, for example by including consecutive patients presenting with a particular set of symptoms or signs. Alternatively, a case-control design may be used in which patients with the target disorder are included along with a sample of healthy controls who do not. While this may be an attractive option, this approach can represent an ‘ideal contrast of extremes’ which tends to result in systematically better performance of diagnostic tests.

Irrespective of the sampling approach used to recruit patients, participants undergo both the new diagnostic test (‘index test’) and a reference standard (sometimes referred to as a ‘gold’ standard but since it is also typically subject to some (small) degree of error or misclassification the term ‘reference standard’ is preferred)—. The reference standard is accepted as the best means of establishing the ‘true’ presence or

absence of the target condition. Investigators then compare findings from the index test in those patients classed as having/not having the target disorder as determined by the reference standard.

3-1 Are the Results of the Study Valid?

3-1-1 Adequacy of the reference standard

The reference standard is the method used to determine the presence or absence of the target condition. To assess the diagnostic accuracy of the index test, its results are compared with those of the reference standard; subsequently, indicators of diagnostic accuracy can be calculated. Estimates of test performance are based on the assumption that the index test is being compared to a reference standard, which is 100% sensitive and specific. If there are any disagreements between the gold standard and the index test results, it is assumed that the index test is incorrect. Thus, from a theoretical point of view, the choice of an appropriate reference standard is very important.

Making a judgement as to the degree of error and misclassification in the reference standard may not be straightforward. Clinical subject-matter knowledge is often needed to judge whether a given test, combination of tests, or consensus panel of experts is an appropriate reference standard.

3-1-2 Delay between administering index test and reference standard

Ideally, the results of the index test and the reference standard are collected from the same patients at the same time. If this is not possible and a delay occurs, misclassification due to spontaneous recovery or to progression to a more advanced stage of disease may occur. This situation is known as disease progression bias. The length of the time that may cause such bias can vary between target conditions. For example, a delay of a few days is unlikely to be a problem for chronic conditions, but for many infectious diseases, a delay of only a few days may be important.

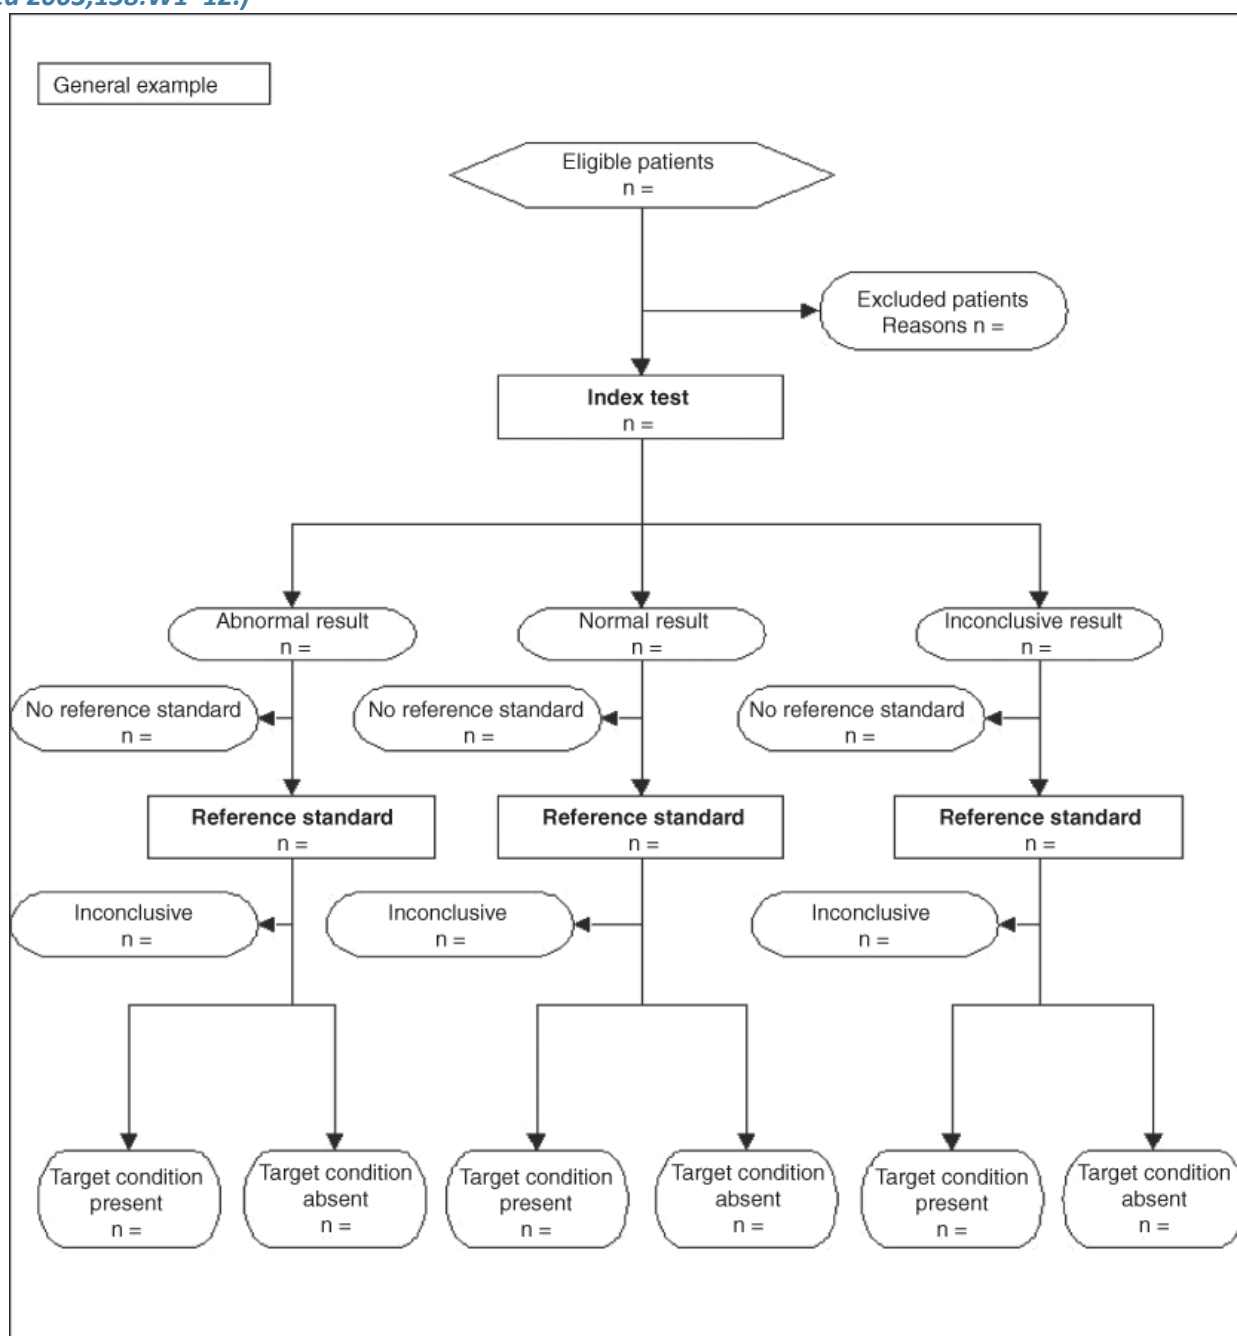

3-1-3 Partial verification

Partial verification bias (also known as work-up bias) occurs when not all of the study group undergo the reference standard. If the results of the index test influence the decision to perform the reference standard, then biased estimates of test performance may arise (Whiting *et al*, 2004). If patients are randomly selected to receive the reference standard, the overall diagnostic performance of the test is, in theory, unbiased. In most cases, however, this selection is not random, possibly leading to biased estimates of the overall diagnostic accuracy. The easiest way to check for bias is by checking the flow chart of the progress of patients through the study (Figure 5).

3-1-4 Differential verification

Differential verification bias occurs when some of the index test results are verified by a different reference standard. This is especially a problem if these reference standards differ in their definition of the target condition—for example, histopathology of the appendix and natural history for the detection of appendicitis. This situation usually occurs when patients testing positive on the index test receive a more accurate, often invasive, reference standard than those with a negative test result. The link (correlation) between a particular (negative) test result and it being verified by a less accurate reference standard will affect measures of test accuracy in a similar way as for partial verification, but less seriously.

Figure 5 Example of a flow chart of a diagnostic accuracy study. (Adapted from Bossuyt et al, *Ann Intern Med* 2003;138:W1–12.)

3-1-5 Lack of independence of index test from reference standard

When the result of the index test is used in establishing the final diagnosis, incorporation bias may occur. This means that the index test to be evaluated is part of or incorporated in the reference standard test. This incorporation leads to circularity—that is, it will probably increase the amount of agreement between index and reference standard test results and hence overestimate the various measures of diagnostic accuracy. Knowledge of the results of the index test alone does not automatically mean that these results are incorporated in the reference standard. For example, a study investigating MRI for the diagnosis of multiple sclerosis could have a reference standard composed of clinical follow-up, cerebrospinal fluid analysis and MRI. In this case, the index test forms part of the reference standard. If the same study used a reference standard of clinical follow-up, and the results of the MRI were known when the clinical diagnosis was made but were not specifically included as part of the reference, then the index test does not form part of the reference standard.

Interdependency all relates to the interpretation of the results of the index and the reference standard test. This situation is similar to 'blinding' in intervention studies. Interpretation of the results of the index test may be influenced by knowledge of the results of the reference standard, and vice versa. This bias is known as review bias and may lead to inflated measures of diagnostic accuracy. The extent to which this bias may affect test results relates to the degree of subjectivity in the interpretation of the test result. The more subjective the interpretation, the more likely the interpreter can be influenced by the results of the reference standard in interpreting the index test, and vice versa. One must consider the topic area and determine whether the interpretation of the index test or reference standard results could be influenced by knowledge of the results of the other test.

3-1-6 Completeness of reporting

A diagnostic test can produce an uninterpretable/indeterminate/intermediate result with varying frequency, depending on the test. These problems are often not reported in diagnostic accuracy studies with the uninterpretable results simply removed from the analysis. This situation may lead to the biased assessment of the test characteristics. Whether bias occurs depends on the possible correlation between uninterpretable test results and the true disease status. If uninterpretable results occur randomly and are not related to the true disease status of the individual then, in theory, these results should not have any effect on test performance. Whatever the cause of uninterpretable results, they must be reported so that their impact on test performance can be determined.

3-1-7 Sample size considerations

Performing and reporting sample size calculation is as important in diagnostic test studies as in RCTs evaluating therapy (Knottnerus and Muris, 2003). One practical approach is to consider for calculations the expected sensitivity: the minimal acceptable lower confidence limit for sensitivity and the prevalence of the disease (Flahault et al, 2005).

3-2 What are the Results?

The results of a simple diagnostic accuracy study with a single diagnostic test ('index test') yielding a dichotomous (positive/negative) result can be displayed in a 2x2 table (see Box 12). From this all basic calculations can be derived.

Box 12. 2x2 table for diagnostic accuracy studies

		Target condition (according to reference standard)	
		Present	Absent
Diagnostic test result	Positive	True Positives (TP)	False Positives (FP)
	Negative	False Negatives (FN)	True Negatives (TN)

3-2-1 Sensitivity and specificity

Sensitivity and specificity are the most widely used statistics in describing a diagnostic test.

- **Sensitivity (Sn)** = proportion of patients with the target condition who have a positive test result (TP/(TP+FN))
- **Specificity (Sp)** = proportion of patients without the target condition who have a negative test result (TN/(TN+FP))

The sensitivity and specificity of a diagnostic test depend on the cut-off selected to define a 'positive' test result. Figure 6 shows the number of patients with and without a disease according to the value of a diagnostic test. This distribution overlaps: the test (like most) does not distinguish normal from disease with 100% accuracy. The area of overlap indicates where the test cannot distinguish normal from disease. In practice, we choose a cut-off value (indicated by the vertical black line) above which we consider the test result to be abnormal and below which we consider the result to be normal. The position of the cut-off value determines the number of true-positive, true-negative, false-positive, and false-negative results. We could use a different

cut-off value for different clinical situations depending on whether the goal is to minimize false-positive findings or false-negative findings.

High sensitivity is favoured when a false-negative result ('missed diagnosis') is more detrimental than a false-positive one ('false alarm'). This might be the case when there is an acceptable, affordable, safe, effective treatment or in early disease where delayed diagnosis is associated with substantially worse prognosis).

High specificity is favoured when a false-positive result is more detrimental than a false-negative one. This might be in circumstances where treatment carries significant risk of harm.

Figure 6 The number of patients with and without a disease according to the value of a diagnostic test. FN, false-negatives; FP, false-positives; TN, true-negatives; TP, true-positives.

3-2-2 Receiver operating characteristic curve

For each diagnostic test, the choice of a cut-off value between normality and abnormality is a compromise between sensitivity and specificity. A receiver operating characteristic (ROC) curve plots for various cut-off values of the same diagnostic test the sensitivity against 1 minus the specificity—that is, the true-positive results against the false-positive results.

The cut-off value minimising both the number of false-positive and false-negative results is the point of the curve nearest the top of the left-hand corner. The closer the curve follows the left-hand border and then the top border of the ROC space, the more accurate the test. Thus, the area under the curve is a measure of test accuracy. An area of 1 represents a perfect test; an area of 0.5 represents a worthless test. Figure 7 shows three ROC curves representing excellent, good, and worthless tests plotted on the same graph.

Figure 7 Comparison of receiver operating characteristic (ROC) curves.

3-2-3 Positive and negative predictive values

In clinical practice, however, the test result is all that is known. We need to know how good the test is at predicting the presence or absence of the target. Predictive values help answer this question.

- Positive predictive value (PPV) = proportion of patients with a positive test result who truly have the targeted condition ($TP/(TP+FP)$)
- Negative predictive value (NPV) = proportion of patients with a negative test result who truly do not have the target condition ($TN/(TN+FN)$)

PPVs and NPVs seem attractive but are of limited utility only because they depend critically on the prevalence of the disease in the patients being tested. The rarer the disease, the more a negative test result indicates no disease and the less a positive test result really indicates a disease. Predictive values observed in one study do not therefore apply to other populations with different background risk (e.g., prevalence) of the disease.

The prevalence can be interpreted as the probability before the test is carried out that the subject has the disease, known as the prior probability of disease. The positive and negative predictive values are the revised estimates of the same probability for subjects with positive and negative test results and are known as posterior probabilities. The shift between the prior and posterior probabilities is another way of assessing the usefulness of the test: it is the likelihood ratio.

3-2-4 Likelihood ratio

When we decide to order a diagnostic test, we want to know which test will best help us rule in or rule out disease in our patient. In the language of clinical epidemiology, we take our initial assessment of the likelihood

of disease ('pre-test probability'), do a test to help us shift our suspicion one way or the other, and then determine a final assessment of the likelihood of disease ('post-test probability').

Likelihood ratios (LRs) tell us how much we should shift our suspicion for a particular test result. Because test results can be positive or negative, there are at least two LRs for each test. The positive LR (LR+) tells us how much to increase the probability of disease if the test is positive, whereas the negative LR (LR-) tells us how much to decrease the probability if the test result is negative.

- Positive likelihood ratio (LR+) = $[TP/(TP+FN)] / [FP/(TN+FP)] = \text{Sensitivity} / (1-\text{Specificity})$
- Negative likelihood ratio (LR-) = $[FN/(TP+FN)] / [TN/(TN+FP)] = (1-\text{Sensitivity}) / \text{Specificity}$

A worked example of the all the above calculations is provided in Box 13.

Box 13. An example of diagnostic accuracy calculations

Investigators evaluated the diagnostic accuracy of simple point-of-care reagent strips for diagnosing presence/absence of inflammatory synovial fluid (SF) in 208 consecutive patients undergoing arthrocentesis. The reference standard was a microscopic white blood cell count of ≥ 2000 cells/mm³ obtained from laboratory analysis of the SF samples.

		Inflammatory SF (reference standard)		
		Present	Absent	
Reagent strip (<i>'index test'</i>)	Positive	60	17	77
	Negative	18	113	131
		78	130	208

Sensitivity (Sn) = $60/78 = 0.77 = 77\%$
 Specificity (Sp) = $113/130 = 0.87 = 87\%$
 Positive predictive value (PPV) = $60/77 = 0.78 = 78\%$
 Negative predictive value (NPV) = $113/131 = 0.86 = 86\%$
 Likelihood ratio (LR+) = $Sn / (1-Sp) = 0.77 / 0.13 = 5.9$
 Likelihood ratio (LR-) = $(1-Sn) / Sp = 0.23 / 0.87 = 0.26$

The LR is used to assess how good a diagnostic test is and to help in selecting an appropriate diagnostic test(s) or sequence of tests. It has advantages over sensitivity and specificity because it can be calculated for several levels of the symptom/sign or test, used to combine the results of multiple diagnostic tests, and used to calculate post-test probability for a target disorder (**Box 14**).

Box 14. Using likelihood ratios to update diagnostic probability

A 50-year-old woman consults for recent wrist arthritis with morning stiffness and without other symptoms. Based on her clinical presentation and his experience of similar cases in the past, the clinician judges that her probability of inflammatory arthritis is about 60%, a pre-test odds ratio (OR) of 6:4. If the clinician was to obtain a positive reagent test strip result ($LR+ = 5.9$) one can calculate the post-test probability of the patient having inflammatory arthritis given the positive test result:

Post-test odds = pre-test odds \times LR = $6/4 \times 5.9 = 8.85$

Post-test probability = post-test odds / (post-test odds + 1) = $8.85/(8.85 + 1) = 0.90 = 90\%$.

A positive reagent test result would change the probability of inflammatory arthritis from 60% to 90%

Switching back and forth between probability and LR's can also be done simply by using a nomogram (**Figure 8**).

An $LR > 1$ produces a post-test probability higher than the pre-test probability. An $LR < 1$ produces a post-test probability lower than that of the pre-test probability. When the pre-test probability lies between 30% and 70%, test results with a very high LR (say, >10) rule in disease. Correspondingly, a very low LR (say, <0.1) virtually rules out the chance that the patient has the disease.

Figure 8 Likelihood ratio nomogram.

3-2-5 Multiple diagnostic tests

Because no diagnostic test is perfect, with sensitivity and specificity of 100%, patients often undergo a series of diagnostic tests during evaluation. Computing the probability of disease depending on the results of five diagnostic tests can be tedious but is easier with LR_s (Box 14).

First, multiply all the LR_s for the various test results together to obtain a global LR. Then apply this global LR as usual to the pre-test probability to obtain the post-test global probability.

Box 15. Combining likelihood ratios from multiple tests to update diagnostic probability

A patient with no history of tick bite has a history of a skin lesion that was not seen by a physician and recurrent attacks of swelling in one knee. This patient has an estimated 40% pre-test probability of Lyme disease. The LR is 19.5 for a positive ELISA test result and 11.14 for a positive western blot test result (Tugwell et al, 1997).

Combine LR_s by multiplying together = $19.5 \times 11.14 = 217.23$

Post-test odds = pre-test odds \times LR = $4/6 \times 217.23 = 144.82$

Post-test probability = post-test odds / (post-test odds + 1) = $144.82 / (144.82 + 1) = 0.993 = 99.3\%$.

The combined effect of both positive tests would change the probability of Lyme disease from 40% to 99.3%

3-2-6 Confidence interval

As for estimation of treatment effect, measures of diagnostic accuracy are only an estimation of the true accuracy of the test calculated from observations of a sample. For all measures of diagnostic accuracy such as sensitivity, specificity, predictive values or LR, a 95% CI is needed to define the range of credible true values.

3-3 How Can I Apply the Results to Patient Care?

3-3-1 Representativeness of study patients

Differences in demographic and clinical features between populations may produce measures of diagnostic accuracy that vary considerably, known as spectrum bias, which may limit clinical applicability (generalisability) of a result (Mulherin and Miller, 2002).

We have already seen that PPVs and NPVs are widely affected by the prevalence of disease, but this is also true, to a minor extent, for sensitivity and specificity and LR (Box 16; Goehring et al, 2004).

Box 16. Sensitivity and specificity are not fixed but may differ across the spectrum of disease severity

In a study evaluating the accuracy of a rapid dipstick test for the diagnosis of UTI (Lachs et al., 1992), investigators found that the rate of false-negatives was higher in patients with diagnosed UTI but presenting fewer characteristic symptoms.

“In the 107 patients with a high (>50%) prior probability of UTI, who had many characteristic UTI symptoms, the sensitivity of the test was excellent (0.92; 95% CI: 0.82 to 0.98). In the 259 patients with a low (\leq 50%) prior probability of UTI, the sensitivity of the test was poor (0.56; 0.03 to 0.79).”

A study of very sick patients (with more marked findings) can make a test look better than it is. For example, a stress thallium test is more likely to produce abnormal results in patients with severe coronary artery disease than in patients with mild disease.

As noted earlier, applying the test only to patients with disease and healthy controls can also make the test look better than it is, because healthy controls are very unlikely to have an abnormal test result.

The spectrum of patients refers not only to the severity of the underlying target condition but also to demographic features and to the presence of a differential diagnosis and/or comorbidities.

It is therefore important that diagnostic test evaluations include patients with and without disease, selected because they have symptoms that would ordinarily cause the physician to order the test and with a spectrum of disease severity from mild to advanced (Knottnerus and Muris, 2003).

Patients may also withdraw from the study before results of the index and/or reference standard tests are known. If patients lost to follow-up differ systematically from those who remain, for whatever reason, then estimates of test performance may be biased.

3-3-2 Reproducibility of the test setting

A sufficient description of the execution of the index and reference standard tests is important for two reasons. First, variation in measures of diagnostic accuracy can sometimes be traced back to differences in the execution of the tests. Second, a clear and detailed description (or citations) is needed to implement a certain test in another setting. Tests executed in different ways would be expected to affect test performance. As an example, the timing and condition of blood samples taken will affect glycaemia results. The extent to which this situation affects results depends on the type of test being investigated.

The value of any test depends on its ability to yield the same result when reapplied to stable patients. Poor reproducibility can result from problems with the test itself (e.g., variations in reagents in radioimmunoassay

kits for determining hormone levels) or from its interpretation (e.g., the extent of ST-segment elevation on an electrocardiogram). This situation is especially important when expertise is required in performing or interpreting the test. Ideally, a report describing a diagnostic test will address the reproducibility of the test results with an appropriate measure.

For a dichotomous outcome, look for a κ coefficient that gives an estimate of the measure of reproducibility, corrected for agreement by chance (Fleiss, 1975). A value of 1 implies perfect agreement. Other values may be interpreted as follows:

- Poor agreement = <0.20
- Fair agreement = 0.20 to 0.40
- Moderate agreement = 0.40 to 0.60
- Good agreement = 0.60 to 0.80
- Very good agreement = 0.80 to 1.00

For a continuous outcome, the two best approaches are the Bland and Altman (1986) graphical method, which plots the difference between two measures against the mean of the two measures, and the intraclass correlation coefficient, which evaluates the level of agreement between raters in measurements (1 is perfect agreement and 0 is no agreement) (Shrout and Fleiss, 1979). A simple correlation coefficient is misleading because it measures correlation and not concordance (Fleiss, 1981).

3-3-3 Consistency of interpretation with clinical practice

Unless the interpretation of the index test results is fully automated and involves no interpretation, the availability of clinical data during the interpretation of test results may affect estimates of test performance. In this context, clinical data are defined broadly to include any information relating to the patient obtained by direct observation, such as age, sex and symptoms. The knowledge of such factors can influence the diagnostic test result if the test involves an interpretative component. If clinical data will be available when the test is interpreted in practice, then these data should also be available when the test is evaluated. If, however, the index test is intended to replace other clinical tests, then clinical data should not be available or should be available for all index tests. Determining what information will be available when test results are interpreted in practice is important before assessing studies for this item.

4 SYSTEMATIC REVIEW OF EVIDENCE: META-ANALYSIS

Meta-analysis is a method of combining the results from a number of studies of similar design to produce an overall estimate of effect that incorporates the information provided by all the studies (Egger et al, 2000).

One area of confusion is the distinction between review articles, systematic reviews, and meta-analyses. Many review articles are unsystematic, because the author does not look at all of the evidence. A systematic review has a formal approach to gathering, evaluating, and presenting the evidence; some systematic reviews are meta-analyses. A meta-analysis goes the final step by using formal statistical methods to calculate a pooled estimate when it is appropriate both clinically and statistically to pool identified studies. Sometimes a group of disparate studies are identified and it makes little clinical sense to pool them all together in a meta-analysis, but a subset of the identified studies may have similar patient populations, with no good clinical reason for the effects of treatment to differ. In this case, a meta-analysis allows for a more precise estimate of effect. Statistical heterogeneity can occur when seemingly homogenous studies are pooled but a large statistical variation in outcome exists, which may reveal undetected differences in patient populations or different intervention characteristics.

The Cochrane Collaboration is an international not-for-profit and independent organisation dedicated to making available up-to-date, accurate information about the effects of health care worldwide. It produces and disseminates systematic reviews and methodological guidelines to improve their quality (Higgins and Green, 2006). Thus, it is a valuable source of methodologically rigorous meta-analyses (Jadad et al, 1998*).

Various amounts and forms of data might be available for a meta-analysis: individual data for each patient or summary statistics from published papers (Whitehead, 2002). A meta-analysis involving individual patient data allows for a more extensive exploration of the data, particularly when individual patient data on prognostic or demographic variables are available. Therefore, many meta-analyses use summary statistics collected from each trial. We focus here on the critical appraisal of meta-analyses based on summary statistics from published reports reporting the results of RCTs.

The process of a meta-analysis consists of defining the question, defining the criteria for studies to be included, identifying and retrieving these studies, abstracting the essential information, performing an appropriate analysis, and reporting the results.

When reading an article reporting a meta-analysis, one should look at these different steps to critically appraise and decide whether or not the results are relevant to the respective patient population (Oxman et al, 1994*; Murad et al., 2014*).

4-1 Are the Results Valid?

4-1-1 Precision of the clinical question

The clinical question addressed by a meta-analysis must be narrow and focused enough to be relevant. A single meta-analysis cannot address all issues raised by a disease or an intervention. A well-focused clinical question should include PICO.

Thus, criteria used to select articles must be appropriate to this question. Inclusion and exclusion criteria must be defined precisely: patient population, intervention, outcomes considered, and study design.

Selecting studies for a meta-analysis is analogous to inclusion criteria for selecting patients for a study—both are filters that may reveal selection bias.

4-1-2 Validity of included studies

Inclusion of low-quality primary studies in a meta-analysis is likely to alter the summary measure of the intervention effect (Moher et al, 1998). For example, if the meta-analysis deals with RCTs, whether the randomisation process was concealed from patients or investigators; whether patients, caregivers, or persons assessing outcome were blinded to the treatment allocation; and the extent to which follow-up was complete is important (Hunt and McKibbin, 1997).

Each trial should be evaluated in terms of its internal and external validity. Quality assessment may then be used in the synthesis stage of the review to inform interpretation, e.g. to do an additional analysis obtaining a pooled estimate of treatment effect from only high-quality studies. It is not standard practice to exclude lower quality studies entirely from systematic reviews.

4-1-3 Reproducibility of study assessments

In the selection of studies included, even if clear inclusion criteria have been defined, the assessment of validity and extraction of data are often subjective and may lead to discrepancies in interpretation. We can be more confident of results if two people made these steps separately, compared results giving a measure of agreement such as the κ coefficient, and then resolved differences by consensus.

4-1-4 Completeness

A thorough search is needed to retrieve all studies of interest, whether the results are positive or negative. One major issue is publication bias, which derives from the selective publishing of studies with statistically significant or directionally positive results. This situation can lead to inflated estimates of efficacy in meta-analysis.

An appropriate search should include the use of bibliographic databases such as Medline, Embase, the Cochrane Central Register of Controlled Trials (CENTRAL: containing more than 990 000 records), and databases of current research. Reference lists of the articles retrieved must be checked, and recently published abstracts presented at scientific meetings can be examined, as can less frequently used databases. Personal contact with experts in the area helps decrease publication bias.

Sources, number of studies included in the meta-analysis, and reasons for exclusion may be summarised in a flow diagram.

Since September 2005, the International Committee of Medical Journal Editors has required the registration of all clinical trials as a prerequisite for consideration for publication (De Angelis et al, 2004). The minimal registration dataset originally included the intervention, key inclusion and exclusion criteria, primary and key secondary outcomes, target sample size. Recent US and forthcoming European Union legislation has expanded the requirement to include the reporting of trial findings. Such mandatory registration and reporting of all trials should reduce non-publication of trials (publication bias) and selective reporting of trial findings.

One of the methods to assess publication bias is by looking at the 'funnel plot', if available (figure 9). This graph plots, for each study, the precision of the estimate of the treatment effect against the estimate of the treatment effect. We would expect results of less precise studies (with fewer participants and events) to be more affected by the play of chance and thus more widely scattered about the pooled estimate. Larger studies with more events should show results closer to the pooled estimate.

One must also pay attention to whether major studies in the field of interest have been published since the search and meta-analysis were performed.

It is important not to omit relevant studies in a meta-analysis and also not to include the same study twice. The latter may occur because of duplicate publication of the same data without cross-references to the original report. Patient data analysed more than once in a meta-analysis leads to biased estimates of treatment efficacy and exaggerated accuracy (Tramer et al, 1997).

Figure 9 Funnel plot to assess publication bias. For each study, the precision of the estimate of the treatment (eg, SE) is plotted against the size of the estimate (eg, log RR). With no publication bias, the estimates should be distributed symmetrically around the pooled result log RR = -0.04 according to the sample size or sampling variation (i.e., SE). In the above case, however, the distribution is asymmetric, suggesting that studies with large log RR (i.e., favour control), especially those with small sample size (or large SE), are less likely to be published.

4-2 What are the Results?

4-2-1 The issue of heterogeneity

Estimating a combined effect of a group of studies makes sense only if the effects found in the individual studies are similar enough.

Of course we expect some variation among studies because the individual estimates of treatment effect will vary by chance. What we need to know is whether there is more variation than we would expect by chance alone. This excessive variation is called statistical heterogeneity, or just heterogeneity. One can determine statistical heterogeneity visually or with a statistical test.

Visual method

The size of the treatment effect (and its CI) from each trial can be graphed on a 'forest plot'. If the magnitude or direction of the effect sizes differ greatly among studies, and if the CIs do not substantially overlap, one should suspect heterogeneity.

Statistical method

One must look at the result of a statistical test—a χ^2 ('chi-squared') test or Cochrane Q test. The information typically provided next to the forest plot in a published meta-analysis includes:

- a χ^2 statistic
- a number called the degrees of freedom (usually one less than the number of studies but can be less if some of the studies have no events)
- a p value obtained by referring the first two numbers to statistical tables.

A significant test result ($p < 0.05$ or 0.10) is often used to indicate evidence of heterogeneity; the difference in results among the individual studies is not likely to have been caused by chance. One must be careful when interpreting the p value because it depends highly on the number of studies included. With few studies, the test is not very good at detecting heterogeneity (it has 'low power'). Conversely, with many studies in a meta-analysis, the test can be too good at detecting heterogeneity.

A more useful way is to compare the χ^2 statistic with its degrees of freedom. A statistic larger than its degrees of freedom shows heterogeneity. Another value, I^2 , may be computed to quantify this heterogeneity. An I^2 of more than 50% indicates strong heterogeneity:

$$I^2 = (\chi^2 \text{ statistic} - \text{degrees of freedom}) / \chi^2 \text{ statistic}.$$

Authors should take heterogeneity into account both in the analysis and in the interpretation of results in a meta-analysis.

A meta-analysis involves two main methods of analysis: fixed-effects or random-effects analysis. Methods of fixed-effects meta-analyses (such as the Mantel-Haenszel or Peto method) are based on the mathematical assumption that a single common (or fixed) effect underlies every study in the meta-analysis. Under this assumption, if every study were infinitely large, every study would yield an identical result, which is the same as assuming no (statistical) heterogeneity among the studies. A random-effects analysis (such as the DerSimonian and Laird method) assumes that individual studies estimate different treatment effects (Lau et al, 1997). With statistical heterogeneity, there is debate about whether a fixed- or random-effects analysis is best. The best option is probably to perform both and then choose the most conservative result.

In the interpretation, authors should try to explain between-study variability in findings. Possible explanations include differences between patients (e.g., thrombolytic therapy in acute myocardial infarction may be more effective for patients who present shortly after the onset of chest pain than for those who present much later), between interventions (e.g., tissue plasminogen activator (tPA) may have a larger treatment effect than streptokinase), between outcome measurement (e.g., the effect may differ if the outcome is measured 30

days rather than 1 year after myocardial infarction), or methodology (e.g., the effect may be smaller in blinded trials or in those with more complete follow-up). Subgroup analysis and meta-regression are methods to help in detecting heterogeneity.

Subgroup analyses may be useful for addressing particular questions when data for different subgroups of patients are available from each study. As for primary studies, with subgroup analysis, results should be interpreted with caution, lest they turn into ‘fishing expeditions’. Such analysis should be planned at the protocol stage, based on good scientific reasoning, and kept to a minimum. The more subgroup analyses the reviewer undertakes, the greater the risk of a spurious conclusion. Meta-regression can formally test for evidence of different effects in different subgroups of trials. For example, meta-regression can be used to test whether treatment effects are larger in low-quality studies than in high-quality studies.

4-2-2 Interpretation of the overall results

One should view the overall results of a meta-analysis the same way as viewing the results of primary studies. In a meta-analysis of a therapeutic question, one should look for the pooled RR, RRR or OR if the outcome is dichotomous, and for the pooled effect size if the outcome is continuous. In meta-analysis regarding diagnosis, one should look for summary estimates of the LRs. As for primary studies, in meta-analyses, the CI will tell the precision of the estimation—that is, the range of values with a 95% probability of including the true effect.

Figure 10 shows the results of meta-analyses typically presented in graphic form, which shows, for each study, the point estimate (dots) and the CIs (horizontal bars). The diamond below all the horizontal lines represents the pooled point estimate with its CI. The vertical line in the middle is the ‘line of no effect’—that is, an RR or OR of 1 or an effect size of 0. A CI of a result crossing the line of no effect indicates no significant difference between the two groups (because of really no effect or because the sample size is too small to show a statistically significant effect). The weight of each study in the final pooled estimation is usually proportional to its sample size, as illustrated by the width of its dot.

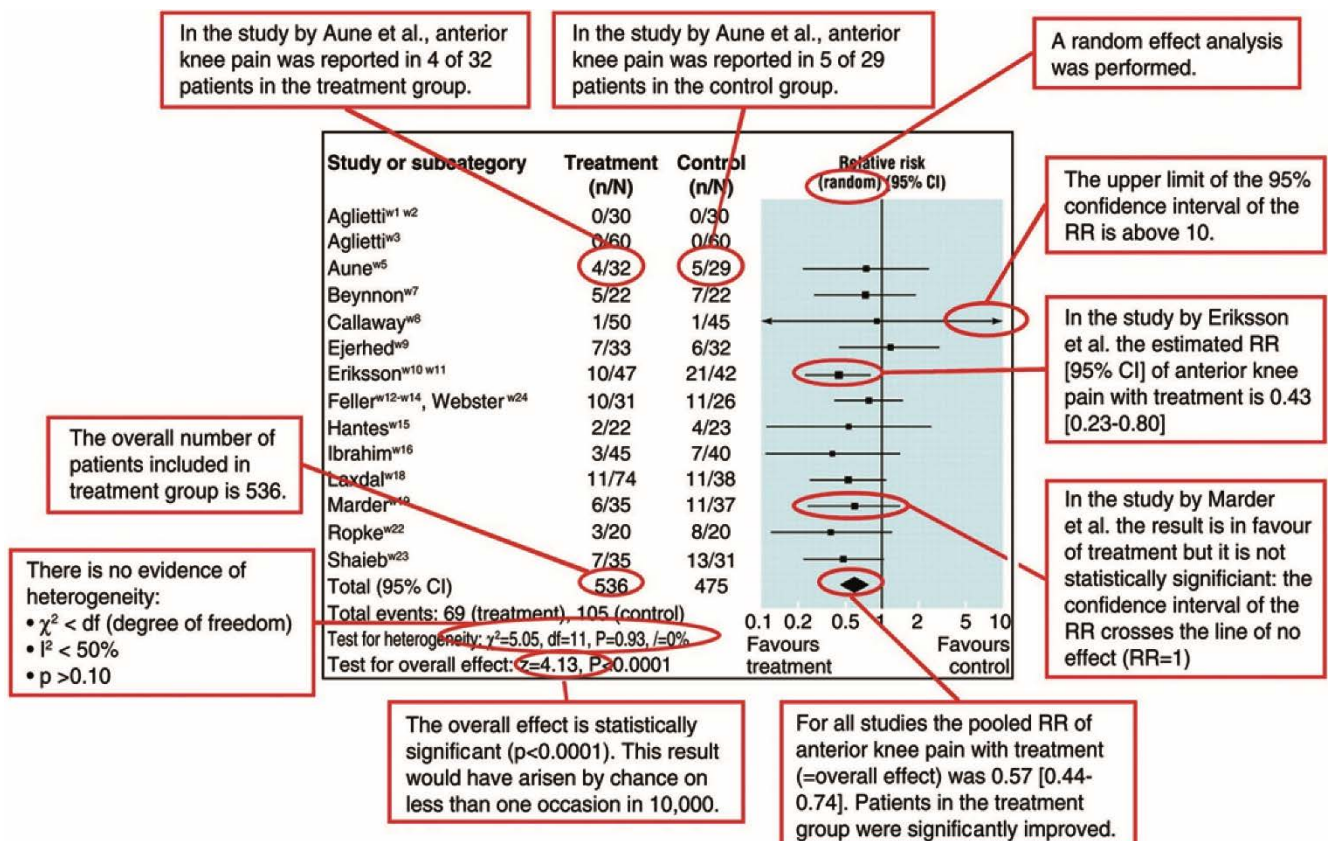

On a single figure, this presentation conveys an impression of the results of the individual studies, conveys the extent of heterogeneity, and reports the pooled estimate.

Various methodological choices must be made when planning and analysing a meta-analysis. Results obtained may depend highly on these choices. Sensitivity analyses may provide confidence in the result by addressing the question ‘Are the findings robust to the method used to obtain them?’. Sensitivity analyses involve comparing the results of two or more meta-analyses calculated using different assumptions.

The following are some examples of situations of sensitivity analyses:

- If a study is of doubtful eligibility for the meta-analysis, then compare the results including and excluding that study.
- Results may be calculated using all studies and then excluding poor-quality studies.
- Both fixed- and random-effects analyses might be undertaken to assess the robustness of the results to the method used.
- If a study appears to be an outlier (has results very different from the rest of the studies), then its influence on a meta-analysis might be assessed by excluding it.
- If missing information is 'imputed' (brought in from another source, perhaps by estimating it), then the effect of imputed numbers should be assessed through sensitivity analyses.

Figure 10 A standard meta-analysis plot of the relative risk (RR) for anterior knee pain after reconstruction of the anterior cruciate ligament. Treatment refers to hamstring autografts; control refers to bone-patellar tendon-bone autografts. (Reproduced with permission from Biau et al, *BMJ* 2006;332:995–1001.)

4-3 How Can I Apply the Results to Patient Care?

Because a meta-analysis involves pooling various studies, undertaken in different settings, the external validity is usually better than that for a single study. However, one must consider the patients in the individual studies and ascertain whether your patient is similar in terms of age, comorbidities, or other risk factors (such as smoking and family history). Does your patient have a comparable baseline risk for the outcome of interest, or is the risk higher or lower in a clinically meaningful way?

All important outcomes, good and bad, relevant to patients must be considered, even if meta-analyses frequently do not report the adverse effects of therapy. One reason for this omission is that the individual studies often measure these adverse effects either in different ways or not at all, so pooling or even effective summarisation of the results is difficult. However, in clinical practice, one should always determine whether the benefits of the intervention in question outweigh the harm to the patient.

SUMMARY POINTS

➤ Intervention studies

- Random allocation of treatment will generate a comparable baseline in all study groups to avoid allocation bias.
- Blinding is the best way to avoid performance and detection bias. Studies should clearly state who (care providers, patients, outcome assessors and/or data analysts) was blinded.
- Intention-to-treat analysis is the most robust analytical method. All patients are analysed in the group to which they were initially randomised, even if they cross over to the other intervention arm, stop their intervention, or are lost to follow-up.
- The primary outcome must be unique, clinically relevant and used for sample size calculations.
- Study results should report both a measure of treatment effect and an estimation of the precision of this measure. Readers need to critically appraise statistical and clinical significance of a result.
- Subgroup analysis is not encouraged unless it is planned prior to the trial and the subgroup-treatment interaction should be used to identify predictors of treatment response.

➤ Diagnostic evidence

- The reference standard test must correctly classify the patient's condition, be independent from the index test, and be performed for all patients.
- Patients included in the study must be selected because they have symptoms that would ordinarily cause the physician to consider ordering the test.

➤ Systematic review of evidence: meta-analysis

- The quality of a meta-analysis relies on the quality of primary studies included.
- Estimating a combined effect of a group of studies only makes sense if the effects found in the individual studies are similar enough.

IN-DEPTH DISCUSSION I

Methodological Issues of Non-inferiority and Equivalence Trials

A non-inferiority or equivalence trial aims to demonstrate that the experimental treatment is not clinically worse than a reference treatment (an active control treatment) by more than a pre-specified small amount (Δ), known as the non-inferiority or equivalence margin (Committee for Medicinal Products for Human Use 2005). The term *non-inferiority* is used when referring to a difference in effects lower than Δ , and *equivalence* when referring to a difference in effects between $-\Delta$ and $+\Delta$ (ICH Steering Committee 1998).

A non-inferiority or equivalence trial is useful when the efficacy of the reference treatment is clearly established and a placebo control group would be deemed unethical. The new treatment is expected to have non-inferior or equivalent efficacy as compared with the standard treatment, while usually claiming other advantages, such as reduced cost, better tolerability, or easier administration (e.g. once daily instead of 3 times a day; or oral instead of parenteral application; or not requiring additional – e.g. invasive – exams before or during therapy). The new treatment may also present an alternative or second-line therapy (Jones et al 1996).

There are number of challenges related to the design, conduct, analysis, and reporting of non-inferiority/equivalence trials, which have been discussed in the literature (D'Agostino et al 2003, Durrleman et al 1990, Ebbutt et al 1998, Garrett 2003, Piaggio and Pinol 2001, Rohmel 1998, Piaggio 2006, Le Henanff et al 2006).

Design

A non-inferiority or equivalence trial requires the efficacy of the reference treatment to be established or in widespread use, and therefore a placebo or untreated control group is deemed unethical (Piaggio 2006).

Sample size and *a priori* margin

Sample size calculation in non-inferiority or equivalence trials is as important as in superiority trials. It depends on the risk of type I error, the risk of type II error and the pre-stated non-inferiority margin, Δ (Blackwelder 1982, Blackwelder and Chang 1984). The margin is often chosen as "the smallest value that would represent a clinically meaningful difference" (Wiens 2002). If relevant, Δ should be smaller than the clinically relevant effect that is chosen to investigate superiority of reference treatment against placebo. The determination of this margin is crucial and must be done *a priori*, based on both statistical reasoning and clinical judgment (ICH Steering Committee 2000). Some reported margins are so large that they are clearly unconvincing. Depending on the choice of the primary outcome of the study, the margin of non-inferiority will be specified as a difference in means or proportions or the logarithm of an odds ratio, relative risk or hazard ratio (Piaggio 2006).

Choice of the reference treatment

The control treatment must be the drug demonstrated to be superior to placebo (and ideally be the gold standard in the particular clinical situation the study is investigating). It is generally not accepted to use a drug for comparison, which demonstrated to be equivalent to another drug with known superiority to placebo (to avoid transitive fallacy).

Analysis

For analysis of non-inferiority or equivalence trials both intention-to-treat (ITT) and per-protocol analyses should be performed (ICH Steering Committee 1998, Garrett 2003, Brittain and Lin 2005). Because of protocol violators and withdrawals, ITT analysis often leads to smaller observed treatment effects than if all patients had adhered to treatment. In superiority trials, ITT is a conservative approach and is recommended. For non-inferiority or equivalence trials, ITT analysis may often increase the risk of falsely claiming non-inferiority (type I error) and lead to biased conclusions.

However, dropouts and non-adherent participants from the 2 groups are potentially different, which may also bias a per-protocol analysis. Thus, both analyses, ITT and per-protocol, are required and considered to have equal importance in drawing a conclusion (Garrett 2003, Brittain and Lin 2005) and should therefore be interpreted next to each other to make a convincing claim.

Interpretation of results: Confidence Intervals

In superiority trials, we use statistical significance tests to determine whether the null hypothesis of “no difference” may be rejected, together with confidence intervals (CIs) to indicate the range of possible true values of the difference compatible with the observed data.

In a non-inferiority or equivalence trial, the conventional statistical test, including the p-value, has little relevance (Jones et al 1996): failure to detect a difference does not imply equivalence (Altman and Bland 1995). Vice versa, a difference that is detected may not have clinical relevance and may correspond to practical equivalence. Conclusions must be drawn by comparing the CI with the pre-specified non-inferiority margin, Δ (Jones et al 1996).

Interpretation of results of a non-inferiority trial is based either on the upper limit of a one-sided 97.5% CI, or the upper limit of a two-sided 95% CI. For an equivalence trial, the interpretation is based on the upper and lower limits of a two-sided 95% CI.

Figure 1 interprets several possible scenarios for non-inferiority trials. With an equivalence trial, the interpretation is analogous, but both margins need consideration, as claiming equivalence requires the complete CI to lie between $-\Delta$ and $+\Delta$ (Piaggio 2006).

Switching to or from superiority trials

Once non-inferiority is evident, it is acceptable to then assess whether the new treatment appears superior to the reference treatment, using an appropriate test or CI (i.e., not just the point estimate), preferably defined a priori and with an ITT analysis (Committee for Proprietary Medicinal Products 2001, Lewis 2002, Fleiss 1992).

It is inappropriate to claim non-inferiority post hoc from a superiority trial unless clearly related to a predefined margin of equivalence (Piaggio 2006). That is, both superiority and non-inferiority hypotheses need explicit specification in the trial protocol. It is, however, always reasonable to interpret a CI as excluding an effect of a particular size defined a priori (Piaggio 2006).

Figure 1: Possible scenarios of observed treatment differences for adverse outcomes (harms) in non-inferiority trials (adapted from the CONSORT statements for non-inferiority trials JAMA 2006;295:1152-60 (Piaggio 2006), permission being obtained)

Error bars indicate 2-sided 95% confidence intervals (CIs). Tinted area indicates zone of inferiority. A, If the CI lies wholly to the left of zero, the new treatment is superior. B and C, If the CI lies to the left of Δ and includes zero, the new treatment is non-inferior but not shown to be superior. D, If the CI lies wholly to the left of Δ and wholly to the right of zero, the new treatment is non-inferior in the sense already defined, but it is also inferior in the sense that a null treatment difference is excluded. This puzzling case is rare, since it requires a very large sample size. It can also result from having too wide a non-inferiority margin. E and F, If the CI includes Δ and zero, the difference is non-significant but the result regarding non-inferiority is inconclusive. G, If the CI includes Δ and is wholly to the right of zero, the difference is statistically significant but the result is inconclusive.

regarding possible inferiority of magnitude Δ or worse. H, If the CI is wholly above Δ , the new treatment is inferior.

**This CI indicates non-inferiority in the sense that it does not include Δ , but the new treatment is significantly worse than the standard. Such a result is unlikely because it would require a very large sample size.*

†This CI is inconclusive in that it is still plausible that the true treatment difference is less than Δ , but the new treatment is significantly worse than the standard.

Clinical epidemiology – critical appraisal of evidence

George Peat, Ian Scott, Weiya Zhang

A previous version was co-authored by Michelle Hui, Daniel Aletaha, Weiya Zhang, Philippe Ravaud, David Torgerson, Candice Estellat

IN-DEPTH DISCUSSION II

**Specific Methodological Issues with Non-pharmacological
Interventions**

Non-pharmacological intervention (including surgery, technical operations, rehabilitation, physiotherapy, education or the use of external technical devices) represent a wide range of treatments for rheumatic disease. Assessing non-pharmacologic treatments involves specific methodological issues linked to difficulties associated with blinding, standardisation of the intervention, and lack of placebo control. Assessment and reporting of harm associated with these treatments is also often neglected. Specific methods may be required to assess the quality of reporting of randomised clinical trials (RCTs) of non-pharmacological treatment.

Blinding

Blinding is a cornerstone of therapeutic evaluation. Lack of reporting on blinding is associated with an increased risk of bias in estimating the “true” effectiveness of a treatment (Juni et al 2001, Noseworthy et al 1994, Pildal et al 2005, Schulz et al 1995) and could lead to performance bias (i.e., unequal administration of care, such as co-interventions or follow-up schedules) or detection bias (i.e., biased assessment of outcome). Lack of blinding of investigators also increases the risk of poor allocation concealment. Hence, when investigators are not blinded, it is particularly important to have a centralised randomisation of patients to avoid allocation bias (Ravaud and Boutron 2006).

Blinding is less frequently reported in RCTs assessing non-pharmacological treatments (Boutron et al 2003), possibly because of the difficulty in achieving and maintaining it (Boutron et al 2004). Fabrication of placebo is more difficult for surgery, rehabilitation or physiotherapy than for pharmacological treatment. However several other ingenious methods to obtain blinding of health-care providers, patients, and/or outcome assessors have been described and inventoried (Boutron et al 2007).

Blinding of health care providers and or patients may involve sham interventions or use of sham devices. For example, Moseley and colleagues used a sham surgical procedure in a trial assessing arthroscopic surgery for osteoarthritis of the knee. The placebo group received skin incisions and underwent a simulated debridement without insertion of the arthroscope (Moseley et al 2002).

These methods do, however, raise important issues. First, it can be considered ethically unacceptable to use sham interventions, because these treatments are not devoid of risk. Second, placebo treatments in clinical trials should not have any specific activity, but the inactivity of sham non-pharmacological interventions is debatable. For example, the use of sham acupuncture (involving needles placed at trigger points) as a placebo to acupuncture has been widely discussed. Third, for most non-pharmacological treatments, the relationship between patients and health-care providers affects the therapeutic effect of the non-pharmacological treatment. Consequently, the use of sham interventions underestimates the treatment effect in placebo-controlled trials by ignoring the effect of this relationship (Paterson and Dieppe 2005).

If blinding of patients cannot be achieved, effort must be taken to prevent detection bias by blinding outcome assessors. Issues of blinding outcome assessors depend highly on the nature of the outcome (Boutron et al 2007):

- For an objective (hard) outcome such as death, there is little opportunity for detection bias (Schulz et al 2002), and blinding is not a problem.
- With an outcome measured from a complementary test (radiography, biology, etc.), blinding of outcome assessors is quite easy to achieve with a centralised assessment.
- For physician-driven data that assumes contact between patients and outcome assessors, such as clinical exam or echography, more ingenious solutions are needed to blind outcome assessors: videotaped standardised clinical exam, photographs, outcome assessor distinct from care provider and patient instructed not to tell the treatment they received.
- Finally, for patient-reported outcomes, blinding outcome assessors necessitates blinding patients.

Standardisation and care provider experience

Studies of non-pharmacological treatments can involve complex interventions of various interconnecting parts, with the collaboration of several health-care providers and, in some cases, individualization of interventions (Campbell et al 2000, Devereaux et al 2005, Herbert and Bo 2005). There is evidence, particularly for surgery, that health-care providers' skills could be a determinant of outcome and harm, and, therefore, health-care providers should be considered part of the treatment. For example, the success of hip arthroplasty or knee arthroplasty depends on preoperative care, anaesthetic management, surgical procedure, surgical device, postoperative rehabilitation, surgeons' expertise and volume of activity at the centre. Consequently, planning and analysing trials of non-pharmacological treatments requires standardization of the intervention and measurement of the health-care provider's adherence to this pre-defined intervention. Care provider learning curve, setting and volume of activity of the centre must also be considered.

Safety

Assessment of harm associated with non-pharmacological treatments is largely neglected and relies mainly on case reports (Cherkin et al 2003, Ethgen et al 2005). In fact, in contrast to pharmacological treatments, non-pharmacological treatments do not need to undergo strict pre-clinical and clinical development and post-marketing evaluation, and reporting of adverse events to regulatory agencies is not required. Further, several non-pharmacological treatments for rheumatic diseases, such as rehabilitation, behavioural interventions and use of complementary alternative medicine, are generally perceived as low risk, even though these therapies might be associated with risk of adverse events, which can be serious (Ernst 2001). For instance, vertebral

artery dissection or cauda equina syndrome have been described after spinal manipulation and pneumothorax after acupuncture (Norheim and Fonnebo 1995, Lee et al 1995). Lack of systematically collected data on harm raises some concerns about the evaluation of the risk–benefit balance of these treatments. For example, would we be confident of the cardiovascular safety of some intensive exercise therapy programs proposed for osteoarthritis and rheumatoid arthritis, without the evaluation and recording of the adverse events observed during trials? Moreover, non-pharmacological trials, as many pharmacological ones, are not sufficiently powered to detect a difference in rate of adverse events.

Quality assessment

Assessing the quality of trial reports is particularly important for clinicians' critical appraisal of the health-care literature and for meta-analysis (Moher et al 1999). A checklist of items seems the most appropriate tool because it would allow for examination of key dimensions individually (Juni et al 2001). These checklists have, however, been developed and validated in the context of pharmacological treatments and do not take into account specific methodological issues in assessing non-pharmacological treatment such as the influence of care providers (Khuri et al 1999, Soljak 2002), standardization, feasibility of blinding and the risk of bias in unblinded trials. Therefore, a checklist specific for assessing the quality of reports of non-pharmacological trials, the tool A Check List to Evaluate A Report of a Non-Pharmacological Trial (CLEAR NPT), has been developed by a panel of 55 experts (Boutron et al 2005). This checklist should allow readers and reviewers to assess the quality of articles and protocols in this field.

Psychosocial aspects of the rheumatic diseases

Dennis C. Turk, Kati Thieme

A previous version was coauthored by Kati Thieme, Rinie Geenen, Arnstein Finset (2014) - Rinie Geenen, Arnstein Finset (2012) - Rinie Geenen, Kathleen Mulligan, Mike Shipley, Stanton Newman (2009)

LEARNING OUTCOMES

- Describe and explain the role of psychosocial and behavioural factors in rheumatology.
- Describe and explain the biopsychosocial aspects of (rheumatic) diseases.
- Recognise the psychosocial consequences of rheumatic diseases in clinical practice.
- Describe the psychological (cognitive, affective, and behavioural—for example, coping abilities), and social determinants (stress) and moderators (e.g., social support) of well-being and functioning in rheumatic diseases.
- Demonstrate a basic understanding of the interactions among the rheumatic disease process and psychosocial variables.
- Screen for possible psychological problems in patients.
- Show a basic knowledge of psychological assessment tools.
- Describe what kind of psychological assistance rheumatologists and clinical and health psychologists can offer.
- Apply knowledge about psychological interventions in rheumatology in the treatment of emotional distress and pain in patients with rheumatic diseases.

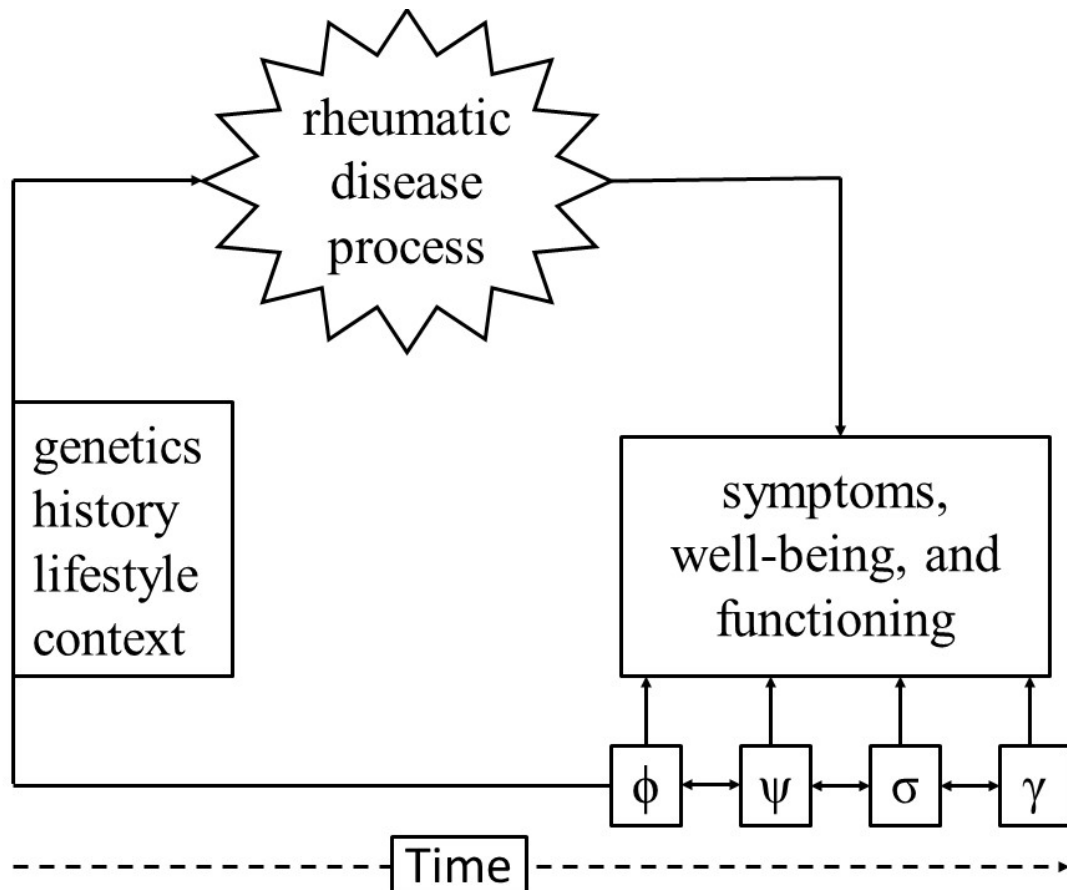

1 Introduction

It is important that clinicians pay attention to the psychosocial, behavioural, and contextual as well as biological dimensions of rheumatic diseases, as these processes are inextricably linked and interact impacting on the perception and response to symptoms and related disability. The disease process has psychosocial consequences and, in turn, psychosocial processes impact on the disease process (Figure 1). Moreover, pre-existing genotypes and prior learning history serve as a background against which the disease is filtered. Behavioural (e.g., avoidance of physical exercise), cognitive (e.g., pessimistic thoughts, fear of activity), emotional (e.g., depression or anxiety) and contextual factors (e.g., availability of emotional support and financial resources, characteristics and limitations of the physical environment) all impact on the disease and illness processes. This set of psychological processes directly impact on symptoms such as pain and fatigue (e.g., hormonal activation, descending pain modulatory effects of brain mechanisms affecting pain perception, avoidance of physical activity) or indirectly on disease activity (e.g., as determinants of adherence to pharmacological treatment, willingness and motivation to engage in activity, and of the likelihood of attending the physician in the event of a disease exacerbation). The Common-sense Model of Illness (Leventhal et al, 1984; Cameron, 2003; Hagger & Orbell, 2003; expanded as the Perceptual-Cognitive Model of Self-Regulation, Leventhal, 1998 and elaborated in Section 2.7 below) is one means of understanding how people try to deal with their disease and accompanying symptoms.

As will be detailed below, many studies have shown that the symptoms and other consequences of the rheumatic disease process are influenced by the way in which people interpret, respond to, and manage their illness and how others respond to their circumstances and needs. This review will describe the influence that rheumatic disease has on psychological wellbeing and physical and emotional functioning, but also the influence that psychosocial factors have on such aspects of management as adherence to recommended treatment and on disease outcomes such as pain, physical and emotional functioning, and health related-quality of life. The possible impact of stress on the rheumatic disease process is discussed in one of the in-depth discussions of this course. Finally, the review will describe methods for assessing patients with rheumatic diseases and provide an overview of treatment of patients' psychosocial problems accompanying these diseases.

Figure 1. Why clinicians should attend not only to the medical dimension but also to the psychological and contextual dimensions of rheumatic diseases.

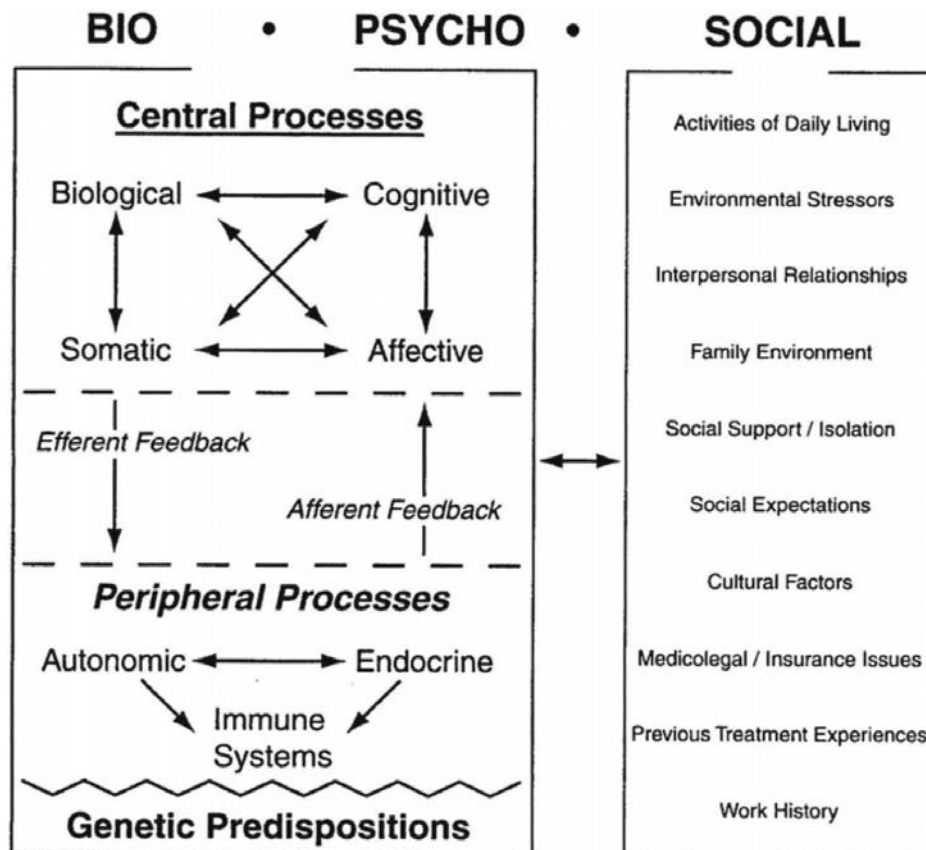

First, the rheumatic disease process itself will impact symptoms, well-being, and functioning. Second, also physiological (ϕ —for example, hormones), psychological (ψ —for example, strategies to cope with problems), social (σ —for example, support or rejection), and contextual (γ —for example, environmental limitation on activity, financial resources available) variables will impact symptoms, well-being, functioning and response to treatment. Third, physiological, psychological, social and contextual variables may impact the rheumatic disease process, itself.

2. Biopsychosocial model

The simplistic model of the psychosocial and behavioural dimensions of rheumatic disease suggests a linear relation, in which the disease severity and damage determine the degree of physical impairment, which in turn influence the illness, disability, and the patient's psychological well-being. This model, is not wrong but rather incomplete. It is not supported by research. A much more complex interrelationship occurs between the disease and its outcomes including modulation from psychosocial factors, genetics, prior experiences, and learning history (Flor & Turk 2011; Figure 2).

Figure 2. A conceptual model of the biopsychosocial interactive processes involved in health and illness.
 From “Comorbidity of Chronic Mental and Physical Health Conditions: The Biopsychosocial Perspective,” by R. J. Gatchel, *American Psychologist*, 59, 792–805. Copyright 2004 by the American Psychological Association.

The terms ‘disease’ and “impairment” have been used to refer to pathological change in the body and the term ‘illness’ and “disability” to refer to the subjective experience of disease (Flor & Turk, 2011). Whereas disease and associated impairments can be examined from a biological point of view, the study of illness and disability from an exclusively biological point of view is insufficient. The study of illness and disability is more fruitful from a Biopsychosocial perspective. A fundamental assumption of this Perspective is that health, illness, and disability are consequences of the synergistic interplay of biological, psychological, social, and environmental factors, which influence the perceived intensity of chronic pain and other symptoms, the degree of disability, and the level of inflammation and other biological factors.

The distinction between disease and illness is analogous to the distinction that can be made between nociception and pain. Nociception involves the stimulation of nerves that convey information about potential tissue damage to the brain. In contrast, pain is the subjective perception that results from the transduction, transmission, and modulation of sensory information. This input may be filtered through an individual’s genetic composition, prior learning history, current psychological status, and sociocultural influences (Gatchel et al, 2007; Flor & Turk, 2011).

As an example, the basic psychobiological mechanisms of chronic pain are influenced by learning such as classical (respondent, Pavlovian) conditioning (reflex-like learning); operant conditioning (learning by approaching positive stimuli and avoiding negative stimuli); observational learning (learning through observation of others), emotional processing, and cognitions (beliefs, attitudes, expectations, meaning analysis). These factors influence sensitisation of central and peripheral responses affecting chronic pain and, in inflammatory rheumatic diseases, hyper-reactive immune responses. Positive interactions among biological, psychological and social factors in chronic pain diseases can provoke healthy mechanisms of pain inhibition and self-regulation in immune response.

A way to understand the Biopsychosocial model is to contrast it with the biomedical (somato-psychic) model, which maintains that illness can be explained solely with biological disease processes independent of psychological and social processes. Independent of psychosocial processes that may result as consequences to physical pathology and the psychogenic model that attributes physical symptoms to psychopathological perturbations. Although the biomedical and psychosomatic models have undeniable benefits, they also have several limitations (Engel, 1977; Taylor, 2003).

A Biopsychosocial perspective incorporates the myriad psychological, social, and contextual factors, in conjunction with biological influences that contribute to the experience, maintenance, and exacerbation of symptoms, as well as response to symptoms and treatments described above. Given the importance of this range of factors, to adequately care for individuals with rheumatic diseases, despite the specific diagnosis, psychological and social-contextual factors, in addition to biological ones, must each be considered and addressed. It is important to acknowledge that rheumatic diseases are chronic conditions, and thus the interplay of physical, psychosocial, behavioural, and contextual factors will evolve over time and should not be viewed as static (Adams & Turk, 2015).

In support of the complex set of factors involved is the wide variability observed in how individual react to ostensibly the same disease and symptoms as well as respond to identical treatment regimens. The longitudinal aspect of person (not just symptom) management and adjustment to illness mean that psychosocial factors are potential causes of symptoms as well as modifiers of symptoms and responses to symptom presence, identifying and dispelling the patient-uniformity myth (e.g., all patients with the same diagnosis are homogeneous requiring a common treatment approach), and acknowledging the importance of environmental context (Adams & Turk, 2015). Although characterization of patient populations complicates the burden of classification (Fillingim et al 2014), it strengthens the potential identification of underlying mechanisms, and helps to guide treatment plans. Research and clinical observation have consistently made us aware that no single treatment works for everyone despite comparable diagnoses. For example, individuals presenting with identical rheumatic diagnoses exhibit a great deal of variability in the degree of pain, number and nature of physical symptoms, and psychological distress that they experience (e.g., Adams & Turk, 2015).

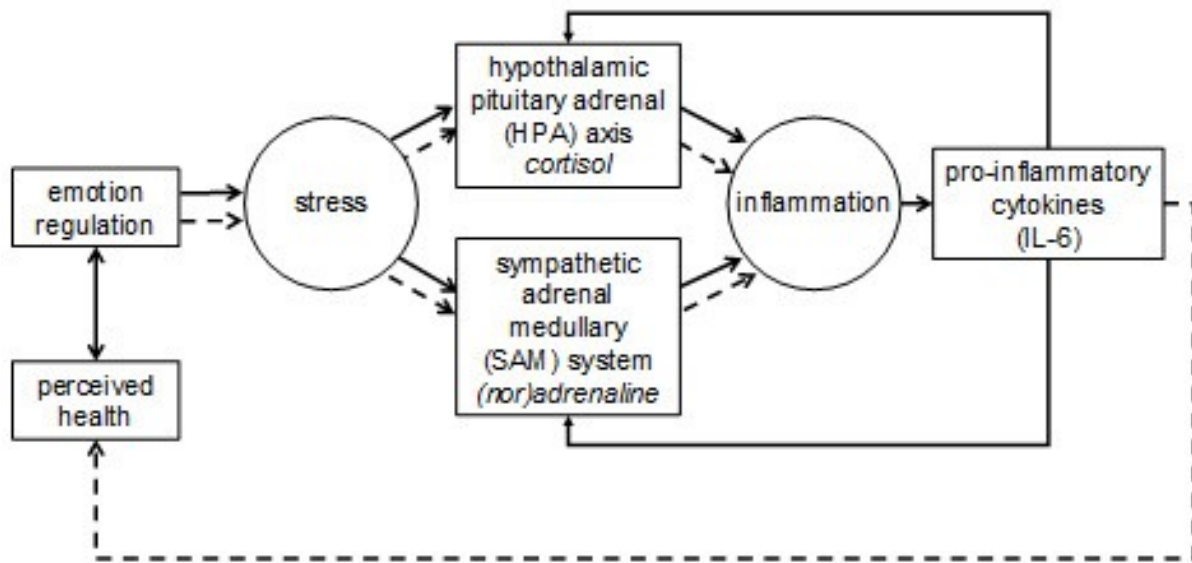

Although we emphasize a Biopsychosocial approach to symptoms, some maintain a view that psychosocial features are direct causes of symptoms. Even in cases in which symptoms occur after some psychological or social perturbation is reported, there is little evidence to support the notion that any psychosocial factor is the sole cause of rheumatic diseases symptoms. Moreover, many who experience comparable events and physical pathology do not develop symptoms and, as noted, even when symptoms do occur there is wide variability in how individuals respond. These psychosocial factors do appear to have an impact on perceptions of symptoms, impact of a disease, and the behaviours of individuals in response to their symptoms. There is little question, however, that psychosocial factors may magnify and maintain symptoms. In the absence of cure, living with a persistent set of symptoms, as characterized by rheumatic diseases, is challenging and the importance and weight of psychosocial factors will vary as individuals adapt and adjust to their persistence over time. The distinction between the causal, moderating, and modulating roles of psychosocial factors is critical for understanding and appropriately treating patients. It is vital that this message be shared with patients who may have preconceived notions about the role of psychosocial factors in their lives and may resist consideration of them if they perceive that these factors are being presented to invalidate their experiences of physical symptoms and contribute to the stigma often associated with these conditions (Adams & Turk, 2015).

2.1 Physiological stress systems

Several possible pathways have been proposed to explain how psychological factors influence disease outcome. One proposal is that psychological factors may have a direct influence on disease through alteration of normal physiological processes. Activation of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS) is a proposed pathway by which perceived or actual stress may have an impact on inflammation (Figure 3; Elenkov et al, 2000; Van Middendorp et al, 2005).

The HPA axis and the SNS are critically involved in the inflammatory process, but can also be activated by stress reactions or be downregulated after persistent physical or emotional stress. Cortisol and catecholamines including norepinephrine (noradrenaline) are end-products of the HPA axis and the SNS systems, respectively. Cortisol and catecholamines have shown both immunosuppressive and immuno-stimulating effects, depending on their concentration and receptor binding capacity. Under chronic inflammatory conditions the stress regulatory system is compromised. Stress and inflammation may amplify sensitisation of pain, and a vicious spiral of stress, pain, and inflammation may occur (Fischer et al, 2016, McEwen & Kalia, 2010; Straub & Kalden, 2001).

Figure 3. Diagram of the bidirectional relationship between psychological factors and inflammation. Solid lines represent positive feed forward, broken lines represent negative feedback (adapted from Van Middendorp et al, 2005)

2.2 The role of cytokines

The unfavourable consequences of the disease process for psychological adjustment are, among other factors, mediated by cytokines, small proteins that serve to regulate the immune system (De Ridder et al 2008). During inflammation, pro-inflammatory cytokines such as tumour necrosis factor- α (TNF- α) and interleukin-6 (IL-6) activate the neuroendocrine stress system. Pro-inflammatory cytokines that signal the brain may also be involved in changing how individuals perceive their health, by reducing psychological, social, and physical wellbeing and functioning-so-called sickness behaviour (Brydon et al, 2009; Dantzer, 2001).

Cytokine induced behavioural effects of inflammation are a common phenomenon in both animals and humans. The administration of inflammatory agents in animals induces a reduction of physical, exploratory, and social behaviour, as well as food and water intake, and it leads to impaired learning and memory. Human sickness behaviour comprises a constellation of non-specific responses, consisting of weakness, malaise, inability to concentrate, depressed mood, lethargy, little interest in the surroundings, and reduced appetite. Both animals that are experimentally injected with an inflammatory agent and humans that have an inflammatory disease are to a certain extent able to resist sickness behaviour depending on, among other factors, motivation and the way they attempt to cope.

2.3 The role of the interaction between heart and brain

Perhaps the cardinal symptom of rheumatic diseases is pain. Pain intensity not only depends on peripheral processes such as inflammation and tissue damage, but also neuronal, immune and neuroendocrine processes are critically involved in pain.

An emerging body of evidence provides support for an important interaction between pain processing and cardiorespiratory regulatory systems (e.g., Bruehl & Chung, 2004; Thieme et al, 2015). It is generally accepted that the stimulation of carotid sinus and cardiopulmonary baroreceptor afferents, which are activated by dynamic changes of blood pressure (BP) and respiratory rate, reduce the pain. It is termed as Baroreflex Sensitivity (BRS). The activated baroreceptors give their signals to the brain stem terminating, in the Nucleus Tractus Solitaries (NTS, Wirtelak, 1997) - the head of the n. vagus that can activate the parasympathetic nervous system. The NTS is responsible both for the inhibition of pain and anxiety besides the improvement of sleep and BP. In healthy individuals, a functional interaction of the cardiovascular and pain regulatory systems has been established whereby elevation in resting arterial blood pressure is related to reduction in acute pain sensitivity. The activation of carotid sinus and cardiopulmonary afferents attenuates pain.

Studies have also shown that persistent pain conditions may be mediated in part by impairments in this interaction between BP and pain sensitivity (e.g., Thieme & Turk, 2006). Diminished baroreceptor sensitivity may have an important impact on pain chronicity (Bruehl & Chung, 2004) and is influenced by classical and operant conditioning (Rau & Elbert, 2001). The permanent stress-related increase of BP leads to a lack of dynamic changes of the pressure in the carotis sinus. The carotid baroreceptors learn not to react anymore. The NTS does not get the information and stops the inhibition. The diminished BRS and NTS activation explain the hypertensive response and have an influence on the development of chronicity in pain.

2.4 Personality

Personality characteristics, the enduring psychological attributes of a person, have in the past been postulated as a cause of arthritis as well as a possible explanation for other aspects of how patients manage their disease. These include individual differences in the ability to cope with the demands of disease and in the adherence to recommended treatment. However, prospective studies of personality as a cause of rheumatoid arthritis (RA) have proved impossible to perform and the elevated levels of neuroticism and lower levels of self-esteem observed soon after diagnosis are now considered to be a reaction to and therefore a consequence of the disease (Krol et al, 1998) that may evolve over time. Neuroticism, a 'proneness to distressing emotional states', has been shown to influence perception of symptoms and wellbeing in RA (Evers et al, 2002; Persson & Sahlberg, 2002). Moreover, personality characteristics such as a self-sacrificing defence style may influence symptoms. For example, pain was associated with impaired physical health related quality of life only in patients with a self-sacrificing defence style (Bai et al, 2009). However, mediating and moderating symptoms cannot be taken as causal mechanisms.

2.5 Behavioural Conceptualizations – Behavioural Learning

Pain is an unavoidable and necessary part of human life. No learning is required to activate nociceptive receptors. However, pain is a potent and salient experience. Beyond mere reflexive actions, people must learn

to avoid, modify, or cope with noxious stimulation. There are three major principles of behavioural learning that help us understand acquisition of adaptive as well as dysfunctional behaviours associated with pain.

2.5.1 Classical (Respondent) Conditioning

In his classic experiment, Pavlov discovered that a dog can be taught, or “conditioned,” to salivate at the sound of a bell by pairing the sound with food presented to a hungry dog. Salivation of dogs in response to food is a natural response, however, by preceding the feeding with the sound of a bell, Pavlov’s dogs learned to associate the sound of the bell with an imminent feeding. Once this association is learned, or “conditioned,” the dogs were found to salivate at the mere sound of the bell even in the absence of the food.

The influence of classical conditioning can be observed in pain patients. Consider physical therapy, a mainstay of treatments for chronic pain patients, where treatment may evoke a conditioned fear response in patients. A patient, for example, who experienced increased pain following physical therapy, may become conditioned and experience a negative emotional response to the presence of the physical therapist, to the treatment room, and to any contextual cues associated with the nociceptive stimulus. The negative emotional reaction may lead to tensing of muscles and this in turn may exacerbate pain and; thereby, further strengthen the association between the presence of the physical therapist and pain.

Once a pain problem persists, fear of motor activities may become increasingly conditioned, resulting in avoidance of activity in the anticipation of avoidance of pain. Avoidance of pain is a powerful rationale for reduction of activity, where muscle soreness associated with exercise functions as a justification for further avoidance. Thus, although it may be useful to reduce movement in the acute pain stage, limitation of activities can be maintained not only by pain but also by anticipatory fear that has been acquired through the mechanism of classical conditioning. Thus, cognitive processes may interact with pure conditioning. It is the anticipation that motivates a conscious decision to avoid specific behaviours or stimuli.

In chronic pain, many activities that were initially neutral or even pleasurable may come to elicit or exacerbate pain. Consequently, they are experienced as aversive and actively avoided. Over time, a greater number of stimuli (e.g., activities) may be expected to elicit or exacerbate pain and will be avoided. This process is referred to as stimulus generalization. Thus, the anticipatory fear of pain and restriction of activity, and not just the actual nociception, may contribute to disability. Anticipatory fear also can elicit physiological reactivity that may aggravate pain. Consequently, conditioning may directly increase nociceptive stimulation and subsequently the perception of pain.

The conviction that patients hold that they should remain inactive is difficult to modify, as long as activity-avoidance succeeds in preventing aggravation of pain. By contrast, repeatedly engaging in behaviour—exposure—that produces progressively less pain than was predicted (corrective feedback) will be followed by

reductions in anticipatory fear and anxiety associated with the activity (Fordyce, Shelton, & Dundore, 1982; Vlaeyen, Kole-Snijders, Boeren, & van Eck, 1995). Such transformations add support to the importance of a quota-based physical exercise program, with patients gradually and progressively increasing their activity levels despite fear of injury and discomfort associated with use of deconditioned muscles. This exposure, in the absence of anticipated pain, provides the corrective feedback that should be positively reinforcing and increase the likelihood of continuation of previously avoided activities.

2.5.2 Operant Conditioning—Contingencies of Reinforcement

The effect of environmental factors in shaping the experience of people with pain was acknowledged long ago (Collie, 1913). However, a new era in thinking about pain began with Fordyce's (1976) extension of operant conditioning to chronic pain. The main focus of operant learning is modification in frequency of a given behaviour -- increasing desirable behaviours and extinction of maladaptive behaviours. The fundamental principle is that if the consequence of a given behaviour is rewarding, its occurrence increases; whereas if the consequence is aversive, the likelihood of its occurrence decreases.

When a person is exposed to a stimulus that causes tissue damage, the immediate behavioural response is withdrawal in an attempt to escape from noxious sensations. Such reflexive behaviours are adaptive and appropriate. Behaviours associated with pain, such as limping and moaning, are called pain behaviours. Pain behaviours include overt expressions of pain, distress, and suffering. A critical defining feature of overt behaviours is that they are observable and thus have a communicative function. If behaviours are observable they are capable of evoking responses and it is the consequences following the behaviour that are particularly important as they can serve to maintain or diminish the likelihood of the behaviour recurring. These pain behaviours can become subjected to the principles of operant conditioning. These behaviours may be positively reinforced directly, for example, by attention from a family member, acquaintance, or health care provider. The principles of learning suggest that behaviours that are positively reinforced will occur more frequently. Pain behaviours may also be maintained by the escape from noxious stimulation by the use of drugs or rest, or the avoidance of undesirable activities. In addition well behaviours (e.g., activity, working) may not be positively reinforced, and the more rewarding pain behaviours may therefore be maintained.

The following example illustrates the role of operant conditioning: When back pain flares up, the individual may lie down and hold her back. The significant other may observe the behaviour and may respond by offering to rub the person with pain back. This response may positively reward the individual and the pain behaviours (i.e., lying down) may be repeated even in the absence of severe pain. In other words, the pain behaviours are being maintained by the learned consequences. The individual's pain behaviours may be negatively reinforced if they permit avoidance of undesirable activities. For example, the significant other may suggest that they cancel the evening plans with a relative, an activity that individual with pain may preferred to avoid in the

past. In this situation, the significant other her husband provided extra attention, comfort, and the opportunity to avoid an undesirable social obligation.

Table 1 describes examples of basic operant principles in chronic pain. The operant learning paradigm does not explain the aetiology of pain or initiation of the behaviour but rather focuses primarily on the maintenance of pain behaviours and deficiency in well behaviours. Adjustment of reinforcement schedules will likely modify the probability of recurrence of pain behaviours and well behaviours.

Table 1. Principles of Operant Conditioning

Schedule	Consequences	Probability of the behaviour recurring
Positive reinforcement	Reward the behaviour	More likely
Negative reinforcement	Prevent or withdraw, avoidance	More likely
Punishment	With negative emotions and much attention	More likely
Punishment	With little attention, ignoring the behaviour	Less likely
Neglect	Prevent or withdraw positive results	Less likely

It is important not to make the mistake of viewing pain behaviours as being synonymous with malingering. Malingering involves the patient consciously and purposely faking a symptom such as pain for some gain, usually financial (secondary gain). In the case of pain behaviours, there is no suggestion of conscious deception but rather the unintended performance of pain behaviours resulting from environmental reinforcement contingencies. Contrary to the beliefs of many third-party payers, there is little support for the contention that outright faking of pain for financial gain is prevalent (Craig, Hill, & McMurtry, 1999).

2.5.3 Social-Learning Processes

From the social-learning perspective, the acquisition of pain behaviours may occur by means of observational learning and modelling processes. That is, people can acquire behavioural responses that were not previously in their repertoire by the observation of others, particularly others who they view as similar to themselves.

Children develop attitudes about health and health care, and the perception and interpretation of symptoms and physiological processes from their parents and social environment. They learn appropriate and inappropriate responses to injury and disease and thus may be more or less likely to ignore or over-respond to symptoms they experience based on behaviours modelled in childhood. The culturally acquired perception and interpretation of symptoms determines how people deal with disease states. The observation of others in

pain is an event that captivates attention. This attention may have survival value, may help to avoid experiencing more pain, and may help to learn what to do about acute pain.

From earliest years, infants, toddlers, and young children are exposed to numerous painful episodes from bumps and falls. Thus, they have plenty of opportunity to observe the reactions they receive. Children of chronic pain patients may make more pain-related responses during stressful times than would children with healthy parents. These children tend to exhibit greater illness behaviours (e.g., complaining, days absent from school, visit to school nurse) than children of healthy parents (Richard, 1988). Models can influence the expression, localization, and methods of coping with pain. Physiological responses may even be conditioned during observation of others in pain (Vaughan & Lanzetta, 1980). Expectancies and actual behavioural responses to nociceptive stimulation are based, at least partially, on prior experience either direct or from observation of others. This may contribute to the marked variability in response to objectively similar degrees of physical pathology observed.

2.6 Behavioural Principles

Video 1 - Pain behaviours in a Patient with dysfunctional Maladaptation

Video 2 - Pain Behaviors in a patient with interpersonal-distressed Maladaptation

Pain, even though originally a reflex, is maintained through reinforcement controlled by operant conditioning formulated by Wilbert Fordyce (1976). He suggested a paradigm shift by expanding the concept of pain from biological processes to include also the influence of "...social/contextual factors that might be little (if at all) related to neurophysiological parameters ...".

Pain behaviours are overt expressions of pain, distress, and suffering such as slowed movement, bracing, limping, and grimacing. Pain behaviours have a communicative function and signal the presence of pain to others. A central feature of pain behaviours is that they are observable, and therefore capable of eliciting a response from significant others. From an operant conditioning perspective, increased pain behaviours result from reinforcing responses by significant others. For example, solicitous responses by significant others have been found to be positively associated with higher ratings of pain severity, more pain behaviours, greater disability and decreased activity levels (e.g., Flor et al, 1995).

Pain behaviours arise through both positive (e.g., excessive solicitous spouse response to pain) and negative reinforcement (e.g., avoidance of unpleasant activities, catastrophizing) subconscious behaviour (Table 1, Box 1). Pain behaviours correlate with an amplified perception of pain intensity that provokes neurophysiological changes influencing the development and maintenance of pain memory (Flor et al, 2002). Operant learning

has been shown to reduce problematic symptoms and behaviours ranging from mental problems such as anxiety and mood disorders (Thieme et al, 2004), to physical problems associated with medication misuse (Turk et al, 1996), deficient activity levels (Romano et al 1995), excessive use of doctor visits (Thieme et al, 2003), avoidance behaviours (Nicassio et al 1997) and amplified pain perception in FM patients with dysfunctional psychosocial adaptation (e.g., Thieme et al, 2005).

Box 1 Operant factors:

Pain behaviour (overt expressions of pain, distress, and suffering)

Betty used to enjoy life, but since she has RA, she only wants to rest. John, her husband, goes to festivities in the family, but when he suggests that she accompanies him or even gets up from the couch and goes outside, Betty answers “that is not good for me, it will make my condition worse, just leave me alone, only rest will help...”. Such kinds of learned cognitions are termed ‘catastrophizing’. Several studies have shown that catastrophizing has a big influence on the course of different pain diseases. Partners and health-care providers can also positively reinforce pain behaviour by pain-related attention and negatively reinforcing pain behaviour by encouraging avoidance of potentially undesirable activities (e.g., performing household chores). For instance, when someone only offers instrumental help or pays attention in case of pain behaviour like moaning, slowing down, or avoiding activities, this behaviour is strengthened and may occur more often in the future. In the operant therapy (OT), patients learn to extinguish (i.e., unlearn) their pain behaviour and to develop healthy behaviour (paced activity, interpersonal interactions) instead; even when experiencing pain. Their significant others are taught to give solicitous responses to the learned healthy behaviour of their diseased partner while ignoring their inappropriate and maladaptive pain behaviours (Bradley et al, 1987, Flor & Birbaumer, 1993, Thieme et al, 2003, 2006).

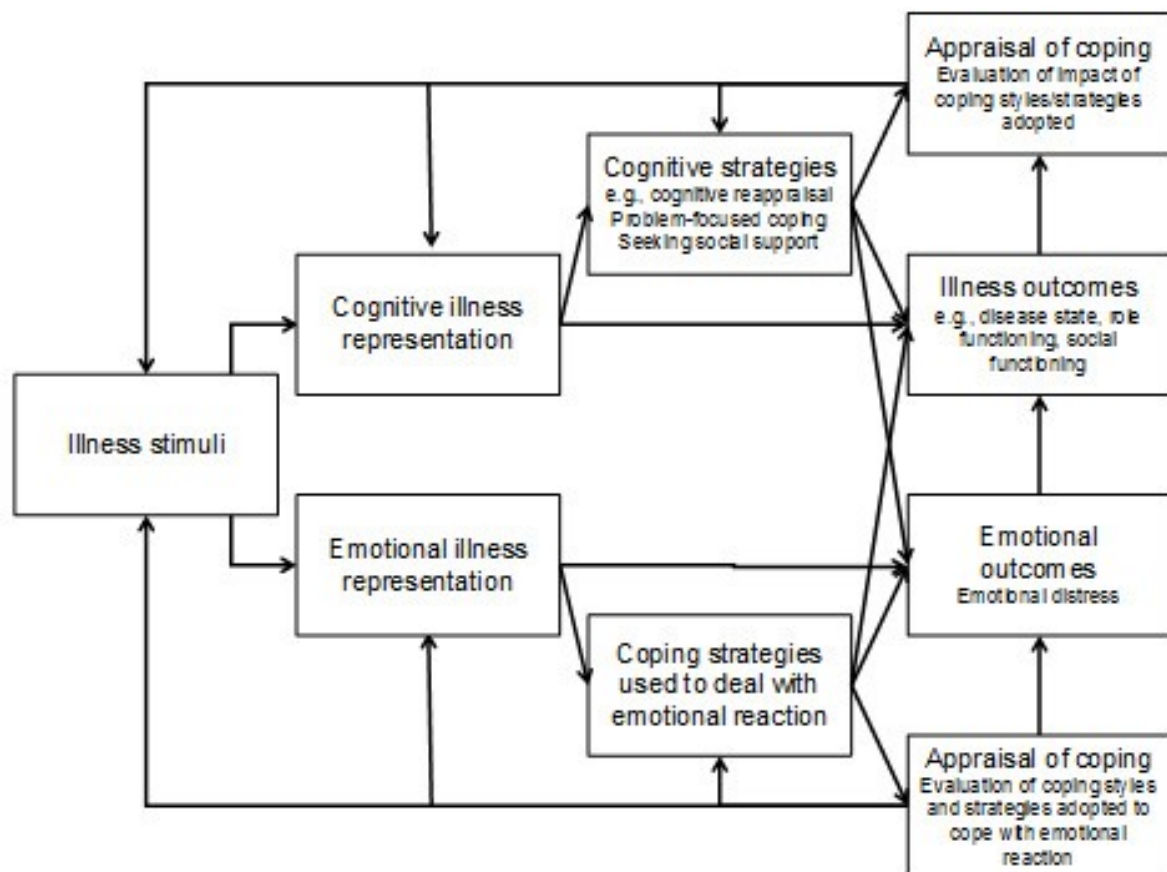

2.7 Illness beliefs and cognitive factors

As outlined in Figure 4 and Box 2, the Perceptual-Cognitive Model of Self-Regulation (Leventhal et al 1998), expanded on the Common-Sense Model of Illness (Leventhal et al, 1984; Cameron et al, 2003), maintains that how people think about their condition influences how they cope with it—their emotional and behavioural response (Turner et al, 2000). There is good evidence to support this view. A cross-sectional study with patients with multiple chronic pain conditions demonstrated that illness beliefs and coping strategies associated with levels of daily functioning (Scharloo et al, 1998) and social support, assessed very early in the disease process, can affect long-term functional disability and pain in RA (Evers et al, 2003).

In support of the Perceptual-Cognitive Model of Self-Regulation, longitudinal studies of RA patients (Scharloo et al, 1999, Van Hoogmoed et al, 2010), demonstrated that illness perceptions and coping strategies contributed to fatigue and health outcomes. Beliefs in the adverse consequences of the disease was associated with more visits to the outpatient clinic, greater tiredness, and higher anxiety scores. Less perceived control and less expression of emotion were associated with more hospital admissions. High scores on coping involving fostering reassuring thoughts were associated with more functional disability. More passive coping was associated with more functional disability and higher anxiety. More perceived symptoms were associated

with more pain, more tiredness, and more depression. More avoidant coping was associated with more tiredness. Belief that the illness will last a long time was associated with higher anxiety. The effect of illness beliefs on disability and quality of life appears to be relatively independent of disease activity (e.g., Graves et al, 2009).

Figure 4. The Perceptual-Cognitive Model of Self-Regulation (Leventhal et al. 1998), expanded on the Common-Sense Model of Illness (Leventhal et al, 1984; Cameron et al, 2003) Adapted from Hagger & Orbell, 2003.

2.7.1 Fear avoidance

Patients' fears about activity increasing pain and other symptoms and causing damage, for example, are likely to intensify actual and perceived limitations physical ability, which are not necessarily a consequence of the severity of their disease or impairments. The Fear-Avoidance Model postulates that pain-related fear and avoidance of physical exercise are essential features of the development, evolution, and maintenance of physical disability for a substantial number of patients with musculoskeletal pain (Vlaeyen & Linton, 2000). In the last decades, an increasing number of investigations have corroborated the interactions among beliefs, emotional response, and behaviours described in the Fear-Avoidance Model (Crombez et al, 2012; Wouters et al, 2012).

Box 2 Perceptual-Cognitive Model of Self-Regulation (Leventhal et al, 1998)

Common-sense Model of health threats distinguishes illness representations and coping procedures:

Illness Representations:

1. Content defines the nature of health threats:

- Identity, the label of the threat—for example, fibromyalgia and its symptoms
- Time line, the prognosis and changeability of the problem
- Cause, the supposed origin—for example, somatic/genetic or stress-induced
- Consequences, the effects such as reduced functioning or work disability
- Cure—control, the extent to which the health problem can be cured, prevented, reduced, or kept from progressing

2. Organization of Representations in acute pattern (flu), cyclic (allergy) and chronic conditions (RA)

Coping Procedures:

- Outcome Expectancies with the dimensions: goal-relevance, time lines, dose efficacy beliefs
- Risk and benefits associated with specific classes of procedures (for example general vs. treatment-specific beliefs affecting adherence to medication protocols)

These beliefs will affect the actions with respect to management of the disease and its consequences.

The beliefs are measured with the revised Illness Perception Questionnaire (IPQ-r, Moss-Morris et al, 2002)

Disease representation and coping procedures share a common identity!

Representations of disease can overlap with representations of the self:

- Attributes of the self can define risk: Perceived vulnerability for breast cancer defines the risk.
- Attributes of the self can moderate procedures for self-regulation - for example, age can moderate the self-regulation process.

2.7.2 Cognitive mediators: Self-efficacy and catastrophizing

Self-efficacy is a person's confidence in their ability to successfully execute and accomplish a given task (Bandura, 1997). Patients' self-efficacy to perform activities of daily living at baseline is a significant predictor of disability as illustrated in a study that assessed activity 12 months from initial assessment (Holm et al, 1998). Converging lines of evidence indicate that perceived self-efficacy operates as an important cognitive factor in adaptive psychological functioning (e.g., Benyon et al, 2010; Sarda et al, 2009), disability (e.g., Benyon et al, 2010; Busch et al, 2007; Sarda et al, 2009), and treatment outcome (e.g., Huffman et al, 2005).

In addition to pain, cognitive-behavioural mechanisms have been shown to directly affect disability. The interference of chronic pain with activities of daily living was, after controlling for current pain severity, accounted for by catastrophizing (a combination of excessively focusing on pain sensations, thinking that something serious might happen, and the perception of not being able to cope with the pain situation - a feeling of helplessness), fear of pain, guarding, and control beliefs (Karoly et al, 2007). Catastrophizing is a

significant mediator of emotional and behavioural reactions to nociceptive sensations and physical impairment. The combination of both situation-specific pain-related and general cognitive variables explained up to 60% of the variance in pain and disability in studies of chronic back pain and RA patients (Edwards et al, 2006, 2011; Flor & Turk, 1988). That means catastrophizing has an important impact on the course of the disease replicated in studies for OA, and fibromyalgia (FM).

2.7.3 Hypervigilance

Hypervigilance for symptoms represents an attentional bias that many people with rheumatic diseases exhibit. An attentional bias is a selective attention towards specific information, most often in relation to threatening information. People who experience recurrent symptoms may develop a pattern of behaviour in which they are constantly on high alert for and anticipate future pain episodes, flare-ups, and increases in pain intensity. This hypervigilance may contribute to patients' avoidance of activity all together or they may cease activity at the earliest sign of symptoms as proposed in the Fear-Avoidance Model.

Hypervigilance for symptoms has been associated with increased symptom intensity, disability, and pain-related health care utilization in a variety of populations of patients with chronic pain (e.g., FM, RA, back pain, Fillingim & Edwards, 2005). It is important to bear in mind that for the individual with the symptoms, being hypervigilant to pain makes perfect sense – paying attention is an important survival mechanism. This is true in the short-term; to protect ourselves against threats. Rheumatic patients may require ongoing education about the difference between monitoring symptoms and excessive focus on symptoms.

2.7.4. Psychological flexibility-rigidity

Psychological flexibility refers to one's ability to act in accordance with his or her own set of values, during interfering thoughts, feelings, or bodily sensations. In acting in alignment with one's values, individuals persist in behaviours that move them toward their broader goals, and need to change behaviours that move them further away from their values. Studies of psychological flexibility demonstrate that higher flexibility is adaptive. Higher psychological flexibility is associated with better psychological outcomes and higher quality of life. Low levels of flexibility, psychological inflexibility, are associated with avoidant coping methods like denial, behavioural disengagement, and self-blame (Adams & Turk, 2015).

In the context of patients with rheumatic diseases, psychological flexibility may be manifested by a person's ability and dedication to maintain involvement in meaningful activities and acceptance that, despite ongoing symptoms throughout their lives, they still strive for and may experience a full life. On the other hand, psychological rigidity is reflected in patients who withdraw from their favourite activities, since they believing that they cannot be active in hobbies. These patients may also obsessively seek ways to eradicate and avoid their symptoms completely, often spending a great deal of time in the search, and to the detriment of actively

engaging in their lives. Obviously, balance is paramount. The Serenity Prayer attributed to the theologian Reinhold Niebhur captures this quite well.

“Give me the serenity to accept things I cannot change, the courage to change the things I can, and the wisdom to know the difference.” [emphasis added]

2.8 Health-Related Quality of Life

Health-related quality of Life (HRQoL) is a relatively new concept. For many years, medical care was directed at the disease and at survival. Nowadays, more care is taken of the patient’s quality of life. Most definitions of HRQoL refer to four components: physical functioning, psychological status, social functioning, and symptoms of the disease or treatment (Taylor, 2003). A more elaborate definition of quality of life is used by the World Health Organization: “an individual’s perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns” (Skevington et al, 2004). RA patients show a lower HRQoL than osteoarthritis (OA) (Wysocka-Skurska et al, 2016), and when musculoskeletal diseases coexist (Picavet, 2004).

Thus, how satisfied or bothered people are with their HRQoL is a highly individual matter. Besides being directed at treatment of disease and symptoms, care should also attend to promoting psychological, physical, and social functioning.

2.8.1 Focus on functioning

Traditionally, rest was considered as appropriate response to a chronic inflammatory disease; currently, exercise therapy is considered a better recommendation (De Ridder et al 2008). Even in chronic inflammatory diseases such as RA, careful long-term intensive exercise has been shown to improve functional ability and emotional status without detrimental effects on disease activity or radiographic damage (De Jong et al 2003; Smidt et al 2005). The challenge of psychological adjustment is often to help the patient to go against the ‘appeal’ of sickness behaviour by overcoming fatigue and depressed mood through exercise, and engaging in activities that promote HRQoL (Box 3).

Based on rank ordering across the HRQoL dimensions of several chronic conditions, physical functioning is especially severely impaired in people with arthritis and other musculoskeletal conditions, but the impact on mental wellbeing is less severe (Alonso et al, 2004; Sprangers et al, 2000). Mental wellbeing and physical functioning in arthritis are related; individuals reporting coexisting psychological distress have poorer scores on physical functioning than those without psychological distress (Hill et al, 2007). Once again, focusing only on the physical aspect, leaves the psychological aspect untreated and may lead to unsuccessful treatment and overtreatment of the physical aspects of the condition.

Box 3 A case for psychology

Traditionally, mental health professionals focused on patients who were unable to adjust adequately to the consequences of chronic diseases. In the past decades, the emphasis on the reasons why people fail to achieve a healthy adjustment has shifted to the identification of factors that help patients make that adjustment. To promote psychological adjustment, individuals with chronic diseases are encouraged to remain active, to acknowledge and express their emotions in a way that allows them to take control of their lives, to engage in self-management, and to try to focus on potential positive outcomes of their illness. Individuals who can use these strategies have the best chance of successfully adjusting to the challenges posed by a chronic illness (De Ridder et al. 2008). Stress resilience factors, and interventions to ease stress and enhance resilience, are gaining increasing attention for the treatment of rheumatic conditions. Cognitive-behavioural and social risk and resilience factors predict the long-term physical and psychological functioning of individuals with rheumatic conditions. Furthermore, screening is useful in clinical practice to identify and select individuals at risk. Stress-management and resilience interventions offer promising ways to improve the long-term functioning. These treatment methods can be especially useful when they are tailored to the specific risk and resilience factors of individuals with chronic diseases, to increase efficiency and availability of treatments, and to optimize patient empowerment in rheumatic conditions.

2.8.2 Life roles

Fatigue, and decreased muscle strength and endurance, along with pain are among the consequences of rheumatic disease that may hamper work, relationships, leisure time, and social activities. Patients with rheumatic diseases will often need to adjust to their life roles. A longitudinal study showed that within the first 3 years almost 50% of patients with RA and more than 25% of individuals with more than 5 years of RA report emotional distress predicted by disability. Disability in valued life activities is very common among individuals with rheumatic diseases. The emotional distress is also associated with alteration of their recreation time, the experienced difficulties in their roles as spouse and parent (Bacconnier et al, 2014). Questionnaire data for 1,210 RA patients at six hospitals in Britain, finds that 46% would like to have discussed the psychological impact of their disease but were never asked about it (Dures et al. 2014). Such role function is measured in the SF-36 and social relationships in the WHOQOL and AIMS.

2.8.3 Work

Work disability and a reduction of family income is a common outcome of rheumatic diseases (Wolfe et al, 2005, Kobelt et al, 2009). In RA, one study showed that education level, body mass index, ESR, rheumatoid factor, pain, and disability assessed with the HAQ, and physical demands of the job were independently associated with work disability (Wolfe et al 2005). A systematic literature review revealed that biomedical variables do not consistently predict work disability in RA; much more important were physical job demands,

low functional capacity, old age, and low education (De Croon et al, 2004). A Swedish study compared RA patients with healthy controls found that low decision latitude was associated with an increased risk of developing RA. Furthermore, some evidence suggests that those with high psychological job demands had a decreased risk of RA (Bengtsson et al, 2009). These results indicate that to deal with work disability in RA the misfit between individual capability and job demands needs to be addressed.

Encouragement to remain in work is an important feature of overall care to individuals with rheumatic disease, and it is important to appreciate that if a patient will be able to continue work will depend on the appropriateness of individual adjustments and the possibility of altering the demands of the work situation (Henriksson et al, 2000). Work accommodations can assist in both job performance and with satisfaction while keeping energy for home and free time and having acknowledgement and help from management and colleagues (Bossemma et al, 2012). When appropriate given age and physical limitations, individuals with chronic diseases should be encouraged to negotiate with employers to improve the match between job demands and capabilities.

2.8.4 Interpersonal relationships

It might be expected that having a painful and potentially disabling chronic disease would have significant negative effects on personal relationships. However, this is not necessarily the case. For example, in one study when asked if they had experienced any interpersonal benefits because of their disease, 71% of people with RA described interpersonal benefits such as ‘appreciation of support from loved ones’ and ‘increased compassion/empathy’, whereas 16% reported another type of benefit (new outlook on life or self), and 13% reported no benefits (Danoff-Burg & Revenson, 2005). Interpersonal benefit-finding predicted lower levels of disability at a 12-month follow-up but not levels of psychological distress or pain. Although the results likely reflect real positive consequences of the disease, caution needs to be exercised in that some patients might focus on positive aspects of their situation in order to protect themselves from painful emotions or deny the severity of their illness and its consequences.

Sexuality is an area often neglected by health professionals; rheumatic diseases impact on the sexual lives of a large minority of those affected and this is a problem that patients and health professionals are reluctant to discuss face-to-face (Hill et al, 2003).). In RA, one-third of individuals report that their sexual activity is influenced by higher levels of fatigue, mental distress, functional limitations, and lower levels of self-efficacy (Helland et al, 2008). They also reported that they are less sexually active than controls and a considerable number of both male and female patients have trouble with their joints during sexual activities, but patients do not differ from controls regarding sexual satisfaction (Van Berlo et al 2007). In FM, especially the psychological aspect of the sexual response cycle (sexual desire and satisfaction) is more disturbed than normal (Prins et al, 2006; Tikiz et al, 2005).

Rheumatic diseases not only have significant impacts on the identified patient. Early results of an ongoing study (K. Thieme) show a higher rate of depression in spouses and more cardiovascular and cancer diseases in spouses who are very solicitous towards their patient-partner.

2.9 Coping

Coping refers to the cognitive, behavioural, and emotional processes by which people attempt to limit the impact of a stressor such as having a rheumatic disease. The coping process involves appraisal of the level of 'threat' posed by the stressor and of one's resources to deal with it (Box 4). If a person feels that he or she is inadequately resourced to deal with the threat, a stress response arises that involves physiological arousal, feelings of anxiety and distress, and stress-related behaviour. Coping strategies have been divided into two broad categories (Lazarus & Folkman, 1984): problem-focused coping (change aspects of the stressful situation) and emotion-focused coping (managing the emotional response that the stressor evokes).

Box 4 Primary and secondary appraisal

Not all individuals respond in the same way to stressors of the disease or life stressors. In order for stress to be evoked for the person, two cognitive events must occur.

1. Primary appraisal: the perception that the event is a threat to one's personal goals—for example, stress may occur when the patient realises that the disease will prevent a successful career.
2. Secondary appraisal: the evaluation that one does or does not have the resources to cope with the demands of the threat—for example, when the patient realises that to be able to live a happy, less ambitious life or to adapt the circumstances at work will reduce stress.

An individual's predominantly used means of coping are likely to change over the course of the disease, as the demands of the disease change and people develop (or fail to develop) resources to deal with them.

Individuals with a diagnosis of early RA report greater future denial than those with established RA, suggesting that denial may be a strategy used for coping in the early stages after receiving a diagnosis (Treharne et al, 2004).

Some patterns of coping have been found to be related to outcomes in rheumatic disease. For example, catastrophizing has been identified as an important strategy in how people cope with pain. In a review, the authors concluded that catastrophizing appeared to be positively related to pain severity and pain-related disability, affective distress, muscle and joint tenderness, and poor pain-treatment outcomes across different rheumatic diseases (Edwards et al, 2006). Proposed explanatory pathways included maladaptive influences on the social environment and amplification of the central nervous system's processing of pain.

The use of passive coping strategies—exerting little control to manage a problem, relying on hoping without taking any action - has generally been associated with poorer outcomes. For example, the use of passive coping strategies and high expectations of disability (Ferrari & Russell 2010) in RA. In a longitudinal study in

patients with a recent diagnosis of RA, passive pain coping predicted functional disability at 3-year but not 5-year follow-up (Evers et al, 2003). This finding suggests that early coping skills training can help people adopt more appropriate strategies to deal with the consequences of the disease. In contrast, the use of more active coping strategies—exerting control to manage a problem—has been shown to be more likely to result in positive outcomes (Buckelew & Parker, 1989).

While the use of active coping strategies is usually found to be helpful, in situations where it is not possible to change the source of stress, continued attempts to solve the problem may result in heightened distress. Expression of emotions may lead to better psychological and physical adjustment as has been found in a variety of chronic conditions (De Ridder et al, 2008).

2.10 Social support

Support from friends and family is potentially an important influence on how well people manage and cope with their disease. In research, this support has been termed ‘social support’ and has been conceptualised both structurally—that is, the size and composition of a person’s social network; and functionally—that is, how a person perceives and evaluates the adequacy of their support network. It is the latter, which appears to be most closely related to health (McNally & Newman, 1999). In a large study as many as 49% of patients with FM were found to report a high degree of loneliness, while the percentages for patients with ankylosing spondylitis or rheumatoid arthritis were 32 % (Kool & Geenen, 2012).

Following Social Support Theory, receiving support from others is generally beneficial to mental and physical health and it may buffer the harmful impact of stressors of the disease or external stressors (Cohen & Wills 1985). In confirmation of this buffering hypothesis, mastery, having many diffuse social relationships and receiving emotional support appeared to mitigate the influence of arthritis on depressive symptoms (Penninx et al, 1997). The important part that social support can play in chronic disease was also shown in a review which concluded that adherence to medical treatment is higher in those from cohesive families but lower in those from families that are in conflict (DiMatteo, 2004).

A review of the empirical literature in several chronic illnesses observed a modest positive relation between social support and self-management (Gallant, 2003). In one prospective study, perceived social support measured at baseline predicted pain 3 years and 5 years later (Evers et al, 2003). Studies have shown that the psychological adjustment of women with RA might be related to the beneficial or problematic spousal support the patient receives from her husband. When the spouse underestimated fatigue (11%), or underestimated (39%) or overestimated physical limitation levels (34%), the person with RA received problematic support such as the spouse find it hard to understand the way the person feel (Lehmann et al, 2011). In contrast, women who reported their spouse as being supportive engaged in more adaptive coping strategies. There is evidence from prospective studies that illness cognitions of more helplessness and less acceptance, more passive coping

with pain or stress, and lower levels of social support predict decreased physical, psychological, and social functioning in individuals with RA in the long-term (e.g., Evers et al. 2002).

A distinction needs to be made between positive support and negative support—that is, care with a negative outcome. Some spouses or other social agents have good intentions, but nevertheless offer an unhealthy kind of social support. Spouses who, for instance, in an assertive and lecturing way ‘know’ what is best for the patient can take away a feeling of independence and control (Kool et al, 2009). Lack of reciprocity in a relationship, both receiving more support than one has provided (over-benefit) and providing more support than one has received (under-benefit) are psychologically distressing (Gleason et al, 2003). Inappropriate and overprotecting support of spouses for patients has been associated with reduced wellbeing and functioning (Hagedoorn et al, 2006; Joekees et al, 2007; Kool et al, 2006). In women with RA, both problematic support and unavailability of support were significantly related to poor family functioning and lower life satisfaction. Both greater problematic support and lower family functioning were (together with higher symptom severity) associated with depressive symptoms (Coty & Walston, 2010).

Also, solicitousness—that is, taking over tasks that the patient could still do—has been shown negative social support (Newton-John, 2002). Self-report data support the hypothesis that spouse-solicitous responses to pain behaviours in patients with chronic pain may contribute to the maintenance of pain behaviours (i.e., overt expressions of pain, distress, and suffering) and disability. In an observational study, spouse-solicitous responses to non-verbal pain behaviours during a household activity were significant predictors of non-verbal pain behaviour in dysfunctional maladapted FM patients who reported greater pain and pain-related interference (Thieme et al., 2005). In this study, spouse-solicitous responses did not predict psychosocial dysfunction or total self-reported pain behaviours.

Considering the different psychosocial aspects associated with chronic pain, there is a heterogeneity of psychosocial adaptations observed among chronic pain patients that is independent on diagnoses. Research by Turk and colleagues (1994) that considers patterns with different levels of pain, interference, physical functioning, spouse responses, pain behaviours and comorbidity (Thieme et al 2004, 2005) has identified several patterns that have been related to chronicity following acute injuries to responses to treatments (e.g., Bergstrom et al, 2011; 2012; Litt & Porto, 2013; Thieme et al 2004, 2006; Verra et al 2009). The subgroups identified are described in box 5.

Box 5 Heterogeneity in Psychosocial Adaptation

Compared to other chronic pain patients:

- *Dysfunctional subgroup* exhibits the highest level of pain, physical disability, and solicitous spouse behaviour and less physical activity. Those patients show significantly more frequently anxiety disorders because of a learned avoidance behaviour reinforced by a solicitous spouse behaviour (see case report 2).
- *Interpersonal-distressed subgroup* reports significantly lower levels of pain, disability, and marital satisfaction. That goes along with a higher level of negative spouse responses on the patient's expression of pain. Those patients learn to show pain behaviours to a little amount with the consequence of a reduced perception of their pain. Instead, they develop more frequently depressive episodes because of a loss of social support (see case report 1).
- *Adaptive Coper subgroup* display a low pain intensity, emotional distress, and interference of pain with daily life and activities associated with distracting spouse behaviours. They show less pain behaviours and a low amount of psychiatric comorbidities such as anxiety and depression.

2.11 Emotion regulation strategies

Psychological adjustment to chronic disease and its consequences depends on coping styles and cognitions (attitudes, beliefs, appraisals, expectancies, interpretation of meaning), but also on the common emotion regulation strategies of a person. Prospective studies generally show that the regular use of avoidant non-expressive styles of emotion regulation, such as alexithymia (having difficulty identifying feelings and distinguishing between feelings and the bodily sensations of emotional arousal and difficulty describing feeling to others), being ambivalent about expressing emotions, emotional repression (being unaware of emotions) and emotional control (avoiding the expression of emotions) are disadvantageous for psychological adjustment and survival, whereas acknowledging and intensely experiencing emotions is suggested to be beneficial for adjustment as long as the emotions are expressed and dealt with (De Ridder et al, 2008). Although expressing emotions is generally adaptive, the mere uncontrolled expression of emotions without processing can be maladaptive.

In a prospective study in patients with RA, alexithymia, and ambivalence over expression of emotions predicted an increase of perceived disease activity 4 months later (Van Middendorp et al, 2005). Measures of alexithymia often co-vary with measures of emotional distress. In a study of female patients with different painful rheumatic conditions and healthy controls no difference in alexithymia was found between the two groups after controlling for anxiety and depression. However, patients had significantly lower scores on the subscale "self" of the Levels of Emotional Awareness scale, indicating a lower capacity to describe their own emotional experience (Baeza-Velasco et al, 2012). Inconsistent evidence for the beneficial effects of emotional expression interventions have been observed in RA (Kelley et al, 1997; Lumley et al, 2011; Van Middendorp et al, 2009; Wetherell et al, 2005) and FM (Lumley et al, 2008).

2.12 Self-regulation

The Perceptual-Cognitive Model of Self-Regulation (Leventhal et al, 1998) ‘common-sense’ perspective of their illness), described earlier (Figure 4 and Box 2), provides a framework through which they understand it and respond to it. This framework, or illness representation, is influenced by many factors, including their experience and knowledge about the illness and information they receive from healthcare professionals, the media, family and friends. The illness also generates an emotional response based on beliefs, expectations, and meaning ascribed to the disease and symptoms. The coping behaviours (i.e., attempts to control or avoid physical and emotional symptoms), including whether they choose to adhere to recommended treatment, that people select to manage their illness are then influenced by both their cognitive representations and their emotional state. People evaluate how effective their coping behaviours have been in managing their illness and this appraisal can then in turn lead to changes in their illness representations and their behaviours. An important feature of this model applied to chronic illnesses is evolution over time. The illness representation will be affected by the effects of the patients’ coping efforts and the disease trajectory.

3. Impacts of rheumatic disease

A survey by the European League Against Rheumatism (EULAR) showed that 70% of people with a rheumatic disease and their carers indicated that their condition affects them emotionally and has a negative impact on their mood often. Yet, only 35% of them raise this issue with their doctor. The sometimes-uncontrollable nature of rheumatic diseases as well as their unpredictable course may make patients more vulnerable to emotional distress. An important psychological dimension of rheumatic disease is the role that several psychological variables have as moderators and mediators of in disease outcomes such as symptoms and physical function.

3.1 Fatigue

Severe fatigue is an extremely prevalent and debilitating symptom in many rheumatic diseases, affecting between 40–60% of patients with a single inflammatory rheumatic disease such as RA, (systemic lupus erythematosus (SLE), ankylosing spondylitis, Sjögren’s syndrome, psoriatic arthritis, and scleroderma, and around 80% of patients with FM. Fatigue may be present regardless of disease activity, and there is no or only a minimal association between fatigue and indicators of the severity of the inflammatory disease as such (Hartkamp et al, 2011; Stebbings & Treharne, 2010). Fatigue is most often associated with pain, sleep disturbances, depression, and negative illness perceptions (Stebbing & Treharne, 2010).

The complexity of fatigue in patients with rheumatic diseases has been emphasised. The Bristol RA Fatigue Multidimensional Questionnaire (BRAFMQ, Nicklin et al, 2010) developed specifically to assess fatigue in

patients with RA, identifies four dimensions of fatigue: physical fatigue, emotional fatigue, cognitive fatigue (concentration problems, lack of mental energy), and daily life consequences of fatigue. Another study identified four patterns of fatigue among patients with RA: 'little impact of fatigue', 'good coping and bad sleep', 'search for balance', and 'high distress' (Nikolaus et al, 2010a). Younger women with RA and with multiple daily roles seem to be particularly vulnerable to the negative impact of fatigue (Nikolaus et al, 2010b).

As fatigue levels decrease in the first hours after awakening and increase throughout the remainder of the day (Goodchild et al, 2010; Van Oers et al, 2010), patients with rheumatic diseases may function best around noon. Fatigue and sleep influence one another. In a study of patients with RA and patients with Sjögren's syndrome, evenings characterised by high fatigue related discomfort were followed by nights with less sleep and worse sleep efficiency. Moreover, nights of poor sleep tended to be followed by days with more severe fatigue compared with the individual's average (Goodchild et al, 2010).

The pathophysiology of fatigue is complex and multifactorial. Among biological factors cytokines, oxidative stress, mitochondrial dysfunction have been investigated (Norheim et al, 2011). Genetic markers of fatigue has also been found for rheumatic disease; e.g., signals of association with primary Sjögren's syndrome (pSS) were detected for one SNP in SLC25A40 and two SNPs in PKN1 in a pSS case versus control analysis (Norheim et al, 2013).

3.2 Affective Distress - Depression

The UK National Institute for Health and Clinical Excellence (NICE) underlines that individuals 'with significant physical illnesses causing disability' have an increased propensity to have high levels of depressed mood (NICE guidelines). Systematic review and meta-analysis compared levels of depressed mood in people with RA, OA, and FM and in healthy controls (Dickens et al, 2002, Matcham et al, 2013). The depressed mood levels of people with RA were significantly higher than the levels of healthy controls (the difference was small to moderate) and of people with OA (the difference was very small), whereas people with FM had higher depressed mood levels than those with RA (the difference was small). A Meta-analysis with 72 studies revealed the prevalence of major depressive disorder to be 16.8% (95% CI 10%, 24%). According to standardized questionnaires, as the Patient Health Questionnaire (PHQ-9, Kroenke et al, 2001), the prevalence of depression was 38.8% (95% CI 34%, 43%), and prevalence levels according to the HADS was 34.2% (95% CI 25%, 44%) for medium and 14.8% (95% CI 12%, 18%) for severe episode of depression. (Matcham et al, 2013). However, the rheumatologists should be aware that loss of appetite and movement might be rather a function of pain than of depression.

Since the prevalence of rheumatic diseases is also higher in women than men, there is a good chance that the rheumatologist will be confronted several times each year by a patient who needs help for depression. In the

case of Judy (Box 6), a referral to a mental health professional would probably show that she is significantly depressed and would benefit for treatment of her depression.

Box 6 A case of depression

Most often Judy came alone to the consultation, but this time her partner Bill came with her. Bill explained: “Lately, Judy just lies down on the couch much of the time. Especially in the morning, she’s seems unable to do anything. Then, she just lays there, she does not read the paper, she does nothing at all. She seems to have no energy or interest in doing any of the things she used like to do” Judy has lost weight in the past months. She awakens very early in the morning; sometimes after having slept for only a few hours. She says she feels worthless and guilty about not being motivated to do the household tasks. She’s glad that the children have all left home “having them around would only make things worse.”

3.2.1 Depression Mortality

Depression has been found to be an independent predictor of mortality in RA. Ang et al (2005) followed 1290 patients for 18 years and found that the hazard ratio of clinical depression on mortality was 2.2 (95% CI 1.2 to 3.9; $p=0.01$) Figure 5. In a meta-analysis of 25 studies, a hazard ratio of depression on mortality between 1.6 and 2.1 was observed and the relative risk in subclinical depression was not substantially smaller than in clinical depression (Cuijpers & Smit, 2002).

Figure 5. Survival over 20-year follow-up of patients with rheumatoid arthritis with and without depression. Reprinted with permission from Ang et al 2005.

3.2.2 Prediction of depression

It is important to appreciate the factors that appear most important in causing depression in rheumatic disease and the extent to which they are modifiable. An obvious hypothesis is that the disease and its consequences may be risk factors for depression: this has been partly confirmed. Depression is often not directly predicted by clinical markers of disease severity, although such a relation has been found in some

studies (Cadena et al, 2003; Martindale et al, 2006). Low socioeconomic status, female sex, younger age, race/ethnicity, higher pain, and functional limitation, as well as poor clinical status appear to be important predictors of depression among persons with RA. Systemic inflammation may also be associated with, cause, or contribute to depression in RA (Margaretten et al, 2011). Longitudinal studies of people with RA show that cognitive and behavioural variables are also important. In one study, the course of depression was predicted by physical disability associated with helplessness cognitions and passive coping (Covic et al, 2003). In another study, disability, pain and beliefs about the consequences of arthritis and coping strategies were the most important predictors of depression (Sharpe et al, 2001).

In people with OA, the strongest risk factors for depression were pain and having few social contacts, followed by physical limitation of the lower body, physical limitation of the upper body, a younger age, and a high body weight (Rosemann et al, 2008). In addition, concerns about physical appearance were, together with levels of disability, predictive of depression in people with RA and in patients with systemic lupus erythematosus (SLE). Concerns about appearance were also found to mediate the relationship between disability and depression (Monaghan et al, 2007).

The relation between depression, symptoms, and physical functioning is complex. It might be expected that a painful, disabling and, to a certain extent, uncontrollable and unpredictable illness could lead to depression, and this relationship gains support from the studies above. However, the relation is not necessarily unidirectional; depression will influence other outcomes in rheumatic disease such as functional abilities.

3.3 Emotional Distress - Anxiety

Anxiety is a major mental health problem that the rheumatologist may confront. The presentation may vary. Negative features of physical limitations or appearance may lead to fear of being evaluated negatively by others. Patients may also have intense anxiety about the presence or severity of physiological symptoms. Intense anxiety and worries (Box 7) are a severe threat to wellbeing and functioning. It is not uncommon to find anxiety combined with depression.

The classification of anxiety disorders (for example, phobias, generalised anxiety disorder, panic with agoraphobia) is according to DSM criteria (Diagnostic and Statistical Manual of the American Psychiatric Association, DSM-5, American Psychiatric Association, 2013) but, as with depression, many people experience heightened feelings of anxiety without meeting the diagnostic criteria for an anxiety disorder. State anxiety refers to an unpleasant emotional arousal in response to a perceived threat, while trait anxiety refers to stable individual differences in a predisposition to state anxiety in anticipation of threatening situations (Spielberger et al, 1983). State anxiety may be a perfectly normal response, but trait anxiety is troublesome for the individual.

Box 7 A case of generalised anxiety

Joanne is the kind of person who is easily worried. She feels stressed almost all the time. She is anxious that her children will be involved in a car accident. When she must stay at home because of her arthritis, Joanne hides from her neighbours, because she does not want them to judge her to be a malingerer. When she has a discussion with her husband, she is afraid that he will leave her for another woman. When there is a problem about insurance on the television, she starts worrying about her own insurance. She is worrying all the time; even when she should be sleeping she is worrying. Therefore, she is easily irritated and fatigued. She envies other people who appear to live their life careless, without any worries.

The core problem for Joanne is that her social, occupational and other important areas of functioning are hampered by excessive, difficult to control anxiety and worry about many events or activities, occurring more days than not. She probably has generalised anxiety disorder.

People with rheumatic disease likely experience anxiety from time to time, because uncertainty about the course and progression is an integral aspect of the disease.

3.3.1 Prediction of anxiety

It appears that anxiety remains stable or decreases slightly over the early years of RA (Evers et al, 2002; Treharne et al, 2007). In one study, disease duration at baseline did not predict the level of concurrent anxiety but greater inflammation, and a longer disease duration at baseline did predict improvement in anxiety by the 1-year follow-up (Treharne et al, 2007). In another study, neither clinical status (erythrocyte sedimentation rate and joint count), pain and self-reported functional disability nor coping or social support predicted anxiety (Evers et al, 2002). The anxiety in rheumatic disease has been shown to be related to an increased sympathetic response associated with diminished BRS and NTS activation (Osailan et al, 2016); beta-blockers may reduce pain and anxiety to 10% (Schneider, 1997).

3.3.2 Prevalence of anxiety disorders

Although fewer studies in rheumatic disease have examined anxiety than depression, some suggest that anxiety is the more prevalent condition. For example, in a cross-sectional study the percentages with an anxiety disorder (panic with agoraphobia, panic without agoraphobia, social phobia, simple phobia, and generalised anxiety disorder) totalled 13% of those without arthritis compared with 20% of those with arthritis (McWilliams et al, 2008). During a longitudinal study extending over 10 years, 30% of patients with RA had increased levels of anxiety at baseline and the prevalence during follow-up varied between 23–25%, whereas 10% of the patients scored within the range for depression with follow-up prevalence varying between 5–13% (Odegard et al, 2007).

In people with RA and OA, state anxiety in RA have normative scores, but trait anxiety, indicating persistently raised anxiety levels, is higher—especially in people with RA who reported comorbid depression (VanDyke et al, 2004). Those with OA did not differ from normative samples on either state or trait anxiety. The difference between RA and OA is interesting, given that they do not differ greatly in rates of depression. This may reflect the greater uncertainty of living with RA, whereas the findings for depression may be at least partly explained by similar levels of pain. Anxiety is also common in other rheumatic disease, such as SLE (Bachen et al, 2009), and in FM, especially in patients with a dysfunctional pain profile (Thieme et al, 2004).

3.3.3 Pain - Psychological Distress Relationship

The relation between pain and emotional distress is not unidirectional. While greater pain has been linked to depression, a history of clinical depression has also predicted current reports of greater pain. Pain reports of participants with RA in stress-induction tests were compared in those who had no history of depression, those who had had one major depressive episode, and those who had experienced two or more episodes (Zautra et al, 2007). The latter group reported most pain, both at entry into the study and in response to the stress induction test compared to the other groups. Similar results were observed for fatigue. People with RA who had a history of affective disorder (major depression or generalised anxiety disorder) reported higher levels of fatigue than those with no previous affective disturbance (Jump et al, 2004).

In a prospective study, baseline variables that predicted fatigue at a 12-month follow-up were less helpful at home, more anxiety and more disability for patients with RA, and more anxiety and less physical activity for a control group (Mancuso et al, 2006). In RA, although an association was observed between psychological distress and disease activity measured at the same time, prospective analyses did not support the notion that psychological distress is a risk factor for future exacerbation of disease activity (Overman et al, 2012)

4. Psychological assessment

We have emphasized the range of psychosocial and behavioural factors that are important in chronic diseases. Optimal treatment of individuals with these conditions will require attention be given to how these factors influence each individual affected. Initially, this will require some assessment of the set of factors described above. A number of tools are available to assess the nature and severity of the psychological impact and the resources available to patients with rheumatic diseases. These may be useful for the clinician to screen patients both for psychological disturbance as well as to gain a greater understanding of patients' beliefs and behaviours. Although a rheumatologist may not have the time or expertise to perform a comprehensive assessment, he or she should be familiar with available measures that may be used by mental health professionals to whom patients may be referred for such an assessment. Not every patient will require an extensive assessment as described but initial screening may help determine which patients might, indeed, benefit from such evaluation.

4.1 Depression

Depression is important because the distress indicates that people are suffering, but also has further implications for how people can manage their rheumatic disease and their physical functioning and, thus, for their health outcome. The NICE guidelines for screening are useful to apply in the first instance in a clinical interview. Several more detailed questionnaire measures are available that can be used to assess the level of depressed or anxious mood and screen for possible clinical 'caseness' (Box 8). The Patient Health Questionnaire (PHQ-S; Kroenke et al, 2001) is a brief, self-administered depression questionnaire, which scores each of the nine DSM-5 criteria as '0' (not at all) to '3' (nearly every day).

4.1.1 Depression Diagnosis

The rheumatologist must always be alert to the possibility of a patient being depressed. There are several brief screening questionnaires exist to assist in the identification of depressed mood (box 9). These are efficient and can be one basis for determining whether a more extensive evaluation by a mental health professional might be appropriate. These brief measures can be used throughout treatment to monitor changing status.

The criteria of the (DSM-5 (American Psychiatric Association, 2013) are used for the classification of mental disorders into qualitatively different diagnostic categories (Box 8, 9). Diagnosis of clinical depression requires a clinical interview performed by an appropriately qualified practitioner such as a psychiatrist or clinical psychologist. Mood varies on a spectrum from high to low and from transient emotional states to a more enduring predisposition to stable negative mood. Moreover, depressed mood may occur without the usual co-existing vegetative symptoms, such as sleep disturbance, change of appetite and low energy.

Box 9 Screening for depression

Diagnosis of clinical depression requires a clinical interview performed by an appropriately qualified practitioner such as a psychiatrist or clinical psychologist. Several screening questionnaires exist to assist in the screening for depressed mood. These instruments also provide cut-off scores that are suggestive of clinical depression and, therefore, the need for further investigation.

1. The 14-item Hospital Anxiety and Depression Scale (HADS) with an anxiety subscale (HADS-A) and a depression subscale (HADS-D; Zigmond & Snaith, 1983)
2. The 5-item Mental Health Inventory (MHI-5; Berwick et al, 1991)
3. The 20-item Center for Epidemiologic Studies Depression Scale (CES-D; Radloff, 1977)
4. The 21-item Beck Depression Inventory (BDI-II; Beck et al, 1996)
5. The 9-item Patient Health Questionnaire (PHQ-2; Kroenke et al, 2003)

Rheumatologists should screen for depression in their regular clinical interview by using two key questions concerning mood and interest, as recommended by the NICE guidelines:

'During the last month, have you often been bothered by feeling down, depressed or hopeless?'

and

‘During the last month, have you often been bothered by having little interest or pleasure in doing things?’

Box 8 The diagnosis Major Depression per the criteria of DSM-5

Depressed mood or a loss of interest or pleasure in daily activities for more than two weeks.

- Mood represents a change from the person's baseline.
- Impaired function: social, occupational, educational.
- Specific symptoms, at least 5 of these 9, present nearly every day:
 1. Depressed mood or irritable most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful).
 2. Decreased interest or pleasure in most activities, most of each day
 3. Significant weight change (5%) or change in appetite
 4. Change in sleep: Insomnia or hypersomnia
 5. Change in activity: Psychomotor agitation or retardation
 6. Fatigue or loss of energy
 7. Guilt/worthlessness: Feelings of worthlessness or excessive or inappropriate guilt
 8. Concentration: diminished ability to think or concentrate, or more indecisiveness
 9. Suicidality: Thoughts of death or suicide, or has suicide plan.

Depressive Episode Criteria (may be part of Major Depressive Disorder OR an isolated episode)

A - Criteria

1. Depressed Mood
2. Loss of interest and enjoyment in usual activities
3. Reduced energy and decreased activity

B - Criteria

1. Reduced self-esteem and confidence
2. Ideas of guilt and unworthiness
3. Pessimistic thoughts
4. Disturbed sleep
5. Diminished appetite
6. Ideas of self-harm

Severity of Depressive Episode:

- Mild: > 1 from column A plus 1-2 from column B. Or 5-6 sx but mild in severity and functional impairment.
- Moderate: > 1 from column A plus 2-3 from column B. Or 7 – 8 sx but moderate functional impairment.
- Severe: All 3 from column A plus > 3 from column B. Or fewer sx but any of these: severe functional impairment, psychotic sx, recent suicide attempt, or has specific suicide plan or clear intent.

4.2 Anxiety

The Hospital Anxiety and Depression Scale (HADS; Zigmond & Snaith, 1983) assesses both depressed mood (seven items) and anxious mood (seven items), and there are several screening questionnaires that can be used to assess anxiety alone—for example, the State-Trait-Anxiety Inventory (STAI) that assesses state anxiety (20 items) and trait anxiety (20 items) (Spielberger et al, 1983). The SCL-90 Symptom Checklist includes a 10-item anxiety subscale among other dimensions of emotional symptoms (Arrindell & Ettema, 2003).

4.3 Pain-related fear

Instruments used to study anxiety and fear responses related to chronic pain are the Pain Anxiety Symptoms Scale (PASS, McCracken et al, 1996), the Fear Avoidance Beliefs Questionnaire (FABQ), the Fear of Pain

Questionnaire (FPQ), and a version of the STAI with variables related to pain severity, perceived disability, and pain behaviour (Spielberger et al, 1983).

4.4 Cognitions

To assess how patients think about their condition the revised Illness Perception Questionnaire (IPQ-r) could be used (Moss-Morris et al, 2002). In addition, the Illness Cognition Questionnaire (ICQ, Eves et al, 2001) assesses three illness cognitions: helplessness as a way of emphasising the aversive meaning of the disease; acceptance as a way to diminish the aversive meaning; and perceived benefits as a way of adding a positive meaning to the disease. To assess pain catastrophizing, the 14-item Pain Catastrophizing Scale can be used (Van Damme et al, 2002). The three factors of this scale are rumination, magnification, and helplessness.

4.4.1 Self-efficacy

To measure self-efficacy, the Arthritis Self-Efficacy Scale (ASES) could be used (Lorig et al, 1989). This 20-item questionnaire assesses self-efficacy in three domains: pain, function, and other arthritis symptoms such as fatigue.

4.5 Coping

To assess how patients are attempting to cope with their condition the Brief COPE (Carver, 1997) could be used (Box 10).

Box 10 Assessment of coping

The brief COPE assesses with 28 items the following 14 coping strategies:

- Self-distraction
- Active coping
- Denial
- Substance use
- Use of emotional support
- Use of instrumental support
- Behavioural disengagement
- Venting
- Positive reframing
- Planning
- Humour
- Acceptance
- Religion
- Self-blame

4.5.1 Coping with pain

Commonly used questionnaires to assess coping with pain are the Coping Strategies Questionnaire (CSQ; Rosenstiel et al, 1983) and the Vanderbilt Multidimensional Pain Coping Inventory that measures 11 coping strategies: problem solving, positive reappraisal, distraction, confrontative coping, distancing or denial, stoicism, use of religion, self-blame, self-isolation, wishful thinking, and disengagement (Smith et al, 1997).

4.5.2 Catastrophizing

Additionally, to the Pain Catastrophizing Scale (van Damme et al, 2002), the 32-item Pain-Related Self-Statements Scale (PRSS; Flor et al, 1993) can be used with the subscales 'active coping' (for example, 'I can handle my pain') and 'catastrophizing' (for example, 'I am a hopeless case').

4.6 Social support

There are many instruments to assess the social resources in the environment of patients. The multidimensional scale of perceived social support includes one social support scale (Zimet et al, 1988). The short form the Social Support Questionnaire measures two dimensions of social support: availability and satisfaction (Sarason et al, 1987). The MOS Social support Survey assesses emotional/informational support, affective support, instrumental support, and positive social interaction (Sherbourne et al, 1991). A negative social attitude towards patients with rheumatic diseases can be assessed with the Illness Invalidation Inventory (3*I) that includes two scales: lack of understanding and discounting (Kool et al, 2010).

4.7 Quality of Life

Four questionnaires are commonly used to assess quality of life in rheumatic diseases (Box 11). Two instruments to assess generic quality of life in rheumatic diseases are the 36-item questionnaire short-form 36 (SF-36) and the 100-item WHO Quality of Life (WHOQoL) questionnaire (Kuyken et al, 1995); a brief 24-item version of this questionnaire has also been developed (Skevington et al, 2004).

Besides generic questionnaires, assessment instruments that are more specific for rheumatic diseases have been developed, such as the 45-item Arthritis Impact Measurement Scales (AIMS; Meenan et al, 1992) and the Health Assessment Questionnaire (HAQ; Fries et al, 1980) and its derivatives (the modified HAQ, clinical HAQ, and multidimensional HAQ).

For some rheumatic disease, specific instruments have been developed. The Fibromyalgia Impact Questionnaire (FIQ-R) measures the impact of FM in the domains of physical functioning, work status, depression, anxiety, sleep, pain, stiffness, fatigue, and wellbeing (Burckhardt et al, 2009). The Western Ontario and McMaster Universities Arthritis Index (WOMAC) is used to evaluate pain, stiffness and functional limitation in OA (Bellamy et al, 1988).

Box 11 The Dimensions of Quality of Life

Four instruments that are commonly used in rheumatic diseases

The Short-Form 36 (SF-36)

1. Physical functioning
2. Role limitations because of physical problems
3. Bodily pain
4. General health
5. Vitality
6. Social functioning
7. Role limitations because of emotional problems
8. Mental health

WHO Quality of Life (WHOQoL)

1. Physical
2. Psychological
3. Level of independence
4. Social relationships
5. Environment
6. Spirituality/religion/personal beliefs

Arthritis Impact Measurement Scales (AIMS)

1. Mobility
2. Physical activity
3. Dexterity
4. Household activities
5. Activities of daily living
6. Anxiety
7. Depression
8. Social activity
9. Pain

Health Assessment Questionnaire (HAQ)

1. Disability
2. Pain

5. Treatment and Psychological intervention

Most rheumatologists will not have the time or expertise to provide in depth psychological interventions for their patients beyond education and encouragement for self-management and responsibility, they need to be familiar with some of the options available and that may be offered to patients they refer to mental health professionals. Some of the most commonly used psychological interventions and their rationales are outlined below.

5.1 Education

Patient education is designed to help individuals understand the nature of their disease, what to expect, and the importance of their role in the self-management of their disease, symptoms, and life with the disease. Education may include advice about activity and some basic self-management skills. More intensive treatment may go into much more depth and include practice and guidance and not just didactic information.

A systematic review of patient education in RA found significant short-term effects of education on disability, joint counts, patient global assessment, psychological status, and depression, and a trend for pain reduction, but there was little evidence of long-term benefits (Riemsma et al, 2004). Another review found improved knowledge, coping behaviour, compliance, and health effects in the short-term, but only some of the studies showed a positive long-term effect on physical or psychological health (Niedermann et al, 2004). A third review concluded that the summary effect sizes suggested that arthritis education programmes result in small reductions in pain and disability (Warsi et al, 2003). Overall, there is a need to find strategies to enhance the transfer of short-term effects into gains in health status.

5.2 Exercise

Aerobic and strength exercise is a means to improve physical function and mental wellbeing. Patients may avoid exercise because of fear of injury and pain (Vlaeyen & Linton, 2010). In clinical practice, the beliefs of patients about possible negative consequences of physical exercise should be addressed because these may hamper the outcome. Evidence about beneficial effects of physical exercise training for patients with RA, OA, and FM has been accumulating (e.g., Busch et al, 2008; Kettunen & Kujala, 2004; Smidt et al, 2005). Physical exercises are combined with the self-management approaches described below.

5.3 Self-management

It has become increasingly recognised that the bulk of the management of chronic conditions is performed by patients and their families (Newman et al, 2009). The limited contact that healthcare professionals have with individuals with chronic conditions means that a lot of time they are on their own and must learn how to cope with taking the medication, with symptoms such as pain and with consequences such as disability.

Encouraging and supporting people with chronic conditions to take more control of their illness by engaging in self-management behaviours has increasingly become a focus in many health services. One push for this approach is the increasing recognition that with an ageing population and consequent increase in chronic disease, health services must change their treatment model (Hyde 2009).

The term 'self-management' implies that a substantial responsibility is taken by patients; this shift of responsibility from the healthcare professional to the individual for the day-to-day management of their condition is achieved by providing information and skills to the participants (Newman et al, 2001, 2004).

Self-management interventions such as CBT (described below) have been shown to be effective in improving coping strategies and reducing the emotional challenges of the disease (Parker & Hart, 2009). Reviews have reported the beneficial effects of self-management interventions on pain, disability, and psychological well-being, over and above effects already being obtained from medication (Newman et al, 2001).

Probably better outcomes could be obtained when more attention is devoted to the content of widely heterogeneous self-management programmes, how they are delivered, the study design, and the attitudes and beliefs of the participants (Newman et al, 2004).

5.3.1 Lay-led self-management

A widely known self-management intervention is the Arthritis Self-Management Programme (ASMP, Barlow et al, 2000). This community-based group programme, led by lay people who themselves are patients, teaches a variety of skills and aims to enhance participants' self-efficacy to deal with their condition. In patients with RA and OA, the ASMP led to positive outcomes with respect to a range of health behaviours (e.g., cognitive symptom management, communication with physicians, dietary habit, exercise, and relaxation) and depression, whereas a trend towards decreases in fatigue and anxiety were noted (Barlow et al, 2000). The findings suggest that the ASMP is effective in promoting improvements in perception of control, health behaviours, and health status, when delivered in UK settings.

A review summarized that lay-led self-management education programmes may lead to small, short-term improvements in participants' self-efficacy, self-rated health, cognitive-symptom management, and frequency of aerobic exercise but that there is currently no evidence to suggest that such programmes improve psychological health, symptoms or health-related quality of life, or healthcare use (Foster et al, 2007).

5.4 Operant-behavioural interventions

The aims of Operant Behavioural Therapy (predicated on principles of operant conditioning see Table 1) are to both reduce pain behaviours, and teach healthy and assertive pain-incompatible behaviours. To achieve these aims, several operant learning strategies are used, such as the contingent positive reinforcement of pain-incompatible behaviour and reduced or absent positive reinforcement of pain behaviours, time-contingent intake and reduction of medication, increased bodily activity, reduction of interference of pain with activities, reduction of pain behaviours, and training in assertive pain-incompatible behaviours. Active participation of significant others is necessary since these important partners will learn to reinforce healthy pain-incompatible behaviours of the patient. The reduction of pain behaviours postulates the insight of both patient and spouse

to distinguish between subconscious “unhealthy” pain behaviours and conscious healthy behaviours. Although a treatment in its own right, physical exercise is an essential part of an operant learning program for training of motor perception, increasing personal physical activities and reducing avoidance behaviour, intake of medication, and excessive solicitous spouse behaviour (Thieme et al, 2003, 2006).

5.5 Cognitive–behavioural interventions

5.5.1 CBT and Treatment of Anxiety

There is growing evidence that CBT is effective in reducing anxiety in patients with rheumatic disease. A meta-analytic review indicated that cognitive-behavioural interventions focused on changing negative cognitions and increasing physical activity levels, is beneficial for many patients with RA (Knittle et al, 2010). In rheumatic diseases, CBT typically involves some combination of cognitive restructuring, behavioural interventions (e.g., increasing physical activity, relaxation), and stress management, and it is mostly delivered in 10 to 20 one hour sessions taking place weekly or once every two weeks by trained clinical psychologists (psychotherapists), nurses, or social workers.

5.5.2 CBT and Treatment of Patients with Depression

Many patients with milder depression respond to interventions such as exercise or guided self-help. Although many improve while being monitored without intervention, structured therapies, such as problem-solving, brief cognitive-behavioural therapy (CBT, Box 12), or counselling can be helpful. Antidepressant drugs and long-term psychological therapies can intensify the treatment. An excerpt from the NICE recommendations are provided in Box 12.

Box 13 NICE treatment guidelines - mild depression

For a significant number of people with mild to moderate depression, brief interventions delivered by the primary care team are effective; for others—particularly if they have not responded to the initial brief intervention—more complex interventions, which could be provided in primary or secondary care, are required.

Many patients with milder depression respond to interventions such as exercise or guided self-help, although many improve while being monitored without additional help. More structured therapies, such as problem solving, brief cognitive–behavioural therapy (CBT) or counselling, can be helpful. Antidepressant drugs and psychological therapies, such as long-term CBT or interpersonal psychotherapy (IPT), are not recommended as an initial treatment; these may be offered when simpler methods (for example, guided self-help or exercise) have failed to produce an adequate response.

General measures that can help some patients with mild depression

1. Sleep hygiene and anxiety management.
2. Watchful waiting. For patients who do not want an intervention or who may recover with no intervention, a further assessment should be arranged, normally within 2 weeks.

3. Physical exercise. Structured and supervised physical exercise may help.

4. Guided self-help programmes based on CBT. Appropriate written materials could be provided with limited support from a healthcare professional, who typically introduces the self-help programme and reviews progress and outcome.

Box 12 Cognitive-behavioural therapy (CBT)

A main premise of CBT is that negative, dysfunctional thought processes have a perpetuating role in health problems. The intervention is directed at reduction of symptoms like depression, anxiety and pain and physiological responses through the manipulation of thoughts and behaviour; examples are interventions with one specific aim—for example, relaxation, stress reduction or overcoming of fear-avoidance beliefs to support an exercise intervention and, more commonly, the incorporation of various methods—for example, cognitive restructuring of dysfunctional beliefs or ‘worry’ thoughts, pain coping skills training, activity pacing, stress management training, relaxation exercises, exposure to anxious situations, thoughts and worries, and positive self-talk.

In moderate to severe depression, antidepressants are the mainstay of therapy, preferably in combination with some form of psychotherapy. For several decades, tricyclic antidepressants were the first-line treatment of depression. Nowadays, antidepressant drugs of choice are, in the first instance, serotonin reuptake inhibitors (Ebmeier et al, 2006). To date, no published comparative study of the newer antidepressants such as those aimed at inhibition of the reuptake of serotonin and norepinephrine (noradrenaline) (SNRIs) has enrolled a large enough group of patients to have the power to detect reliably the differences between two effective treatments (Lieberman et al, 2005). Because pro-inflammatory cytokines may promote depression, the blockade of pro-inflammatory cytokines with biologicals such as infliximab, etanercept or adalimumab may turn out to be a new therapy for depression in RA (Fuggle et al, 2014; Rech et al, 2013).

The psychological treatment of depression will vary depending on its severity. Combined treatment involving medication and evidence based psychotherapy typically provides a modest increment over either single treatment alone (Hollon et al, 2002). In both severe and mild depression, to prevent relapse or recurrence, a clinical psychologist may offer CBT or interpersonal psychotherapy (IPT) (Anderson et al 2000; Ebmeier et al, 2006; Hollon et al, 2002). A main premise of CBT is that negative, dysfunctional thought processes have a perpetuating role in depression, whereas IPT is based on the premise that depression occurs in a social and interpersonal context. Review studies indicate greater long-term effectiveness of CBT over tricyclic antidepressants alone. CBT is a mainstay approach to depression (Ebmeier et al, 2006; Feldman, 2007; Kuyken et al, 2007). The capacity to reduce relapse risk after stopping pharmacological interventions is considered one of the major benefits provided by cognitive and behavioural interventions with respect to the treatment of

depression and anxiety disorders (Hollon et al, 2006). Outcomes for IPT are broadly like the outcomes of CBT (Ebmeier et al, 2006).

5.5.3 CBT and Treatment of Pain and Disability

Reviews of cognitive–behavioural interventions concluded that, over the past decade, controlled research has continued to provide support for the efficacy of psychosocial interventions for OA and RA (Astin et al, 2002, Keefe et al, 2002, Morley et al, 1999, 2011). Research has revealed beneficial effects across a number of arthritis outcomes, including pain management, diminished psychological distress, improved marital adjustment, and reduced disease-related symptoms such as joint swelling and fatigue. Patients with shorter disease duration show higher effects from CBT (Astin, et al 2002).

CBT has been included as a treatment option in the case of FM with moderate to large effects (Carville et al, 2008; Hauser et al, 2010; see Box 12), perhaps most in highly distressed patients (Van Koulil et al, 2010, Thieme et al, 2007). A meta-analysis examined the efficacy of randomised controlled trials of cognitive–behavioural interventions in the treatment of RA (Astin et al, 2002). Significant effect sizes (Box 14) were found post-intervention for pain (0.22), functional disability (0.27), psychological status (0.15), coping (0.46), and self-efficacy (0.35). At follow-up (averaging 8.5 months, significant pooled effect sizes were observed for tender joints (0.33), psychological status (0.30), and coping (0.52). Overall, the findings suggested that psychological interventions may be important adjunctive therapies in the management of RA; perhaps the most for patients who have had the illness for shorter duration.

Box 14 Quantifying the effects of therapy: effect size

In a randomised controlled trial, researchers are not only interested in the significance of effects, but also in the magnitude of effects. A commonly used statistic to express the magnitude of effects is the effects size, or *d* statistic. It expresses the difference between groups (for example, the experimental and control group) in standard deviation units. A *d* of 0.30 means that the difference between two groups is 0.30 standard deviation. To interpret the magnitude of effect sizes, the criteria proposed by Cohen (1988) are commonly used:

Small difference: $d = -0.20$ or $d = 0.20$

Moderate difference: $d = -0.50$ or $d = 0.50$

Large difference: $d = -0.80$ or $d = 0.80$

5.5.4 Acceptance and Commitment Therapy (ACT)

Although, the restructuring of cognitions and behaviour is a fruitful approach to help patients to deal with situations that can be changed, the acceptance of the inevitable consequences of the disease should be part of patients' coping repertoire to deal with situations that cannot be changed. In recent years, Acceptance and Commitment Therapy (ACT; Hayes et al, 2006), a variant of traditional CBT, been applied in the treatment of mental problems that may accompany chronic somatic diseases (including several rheumatic diseases). This

therapy helps patients to accept the difficulties that come with a chronic disease and to be committed to make changes in daily life that are in agreements with one's life values.

ACT is an example of a mindfulness based stress reduction (MBSR) therapy. Mindfulness based interventions focus on becoming aware and accepting all thoughts, feelings, and sensations instead of trying to avoid or fight them. Recent reviews have found significant, small to moderate effects of MBSR on psychological distress, pain and coping behaviour (Bohlmeijer et al, 2010; Merkes, 2010; Veehof et al, 2011). Integrating MBSR in CBT may enhance the efficacy of mindfulness-based interventions (Bohlmeijer et al, 2010). A randomized controlled trial examined the effects of a mindfulness-based group intervention in adults with inflammatory rheumatic diseases (Zangi et al, 2012). Significant better improvements in the experimental group as compared to the control group were found in psychological distress, self-efficacy, emotion-focused coping, fatigue, self-care ability, and overall well-being at post-treatment and maintained at 12 months' follow-up. However, there do not appear to be any studies demonstrating that ACT has any better outcomes when compared to CBT in general (Wetherell et al, 2011). An important question that remains is identifying those patients who are most likely to respond to any of the variants of CBT and other psychosocial treatments (Vlaeyen & Morley, 2005).

6. Adherence/Compliance

For any treatment to be effective (pharmacological or nonpharmacological), patients have to adhere to the requirements, in the absence of cure, patients may have to adhere to treatment recommendations for many years.

Adherence to medication and to other aspects of recommended treatment such as exercise are essential for optimising health and well-being in rheumatic disease. A meta-analysis of 22 studies in arthritis found a mean adherence to medication of 81% (95% CI 72% to 89%, DiMatteo, 2004). Non-adherence to medication may be unintentional—for example, misunderstanding the correct dose to take or forgetting to take it—or it may be intentional—for example, not completing a course of medication once the patient feels better. Psychological factors have been found to have an influence on adherence—for example, the beliefs people hold about their illness and treatment have been shown to influence how well they follow advice. These beliefs are formed not only by the information received from healthcare professionals but may also be influenced by the person's own experience of the illness and by the views of other people and the media. Beliefs about the necessity of medication and concerns about the medication itself have been shown to be important (Horne & Weisman, 1999). For example, concerns expressed about medication have been found to be greater in patients with RA who are non-adherent than in those who are adherent (Neame & Hammond, 2005). Better adherence was also predicted by a stronger belief in the necessity of medication and belief that medications are not overused (Treharne et al, 2004). As predicted by the Perceptual-Cognitive Model of Self-Regulation, expanded from the

Common Sense Self-Regulatory Model (Box 4), cognitive and emotional representations of illness are hypothesized to affect adherence. Although this has not been examined in rheumatic diseases, a study in individuals with asthma revealed that beliefs about antecedent causes and about cure-control predicted current adherence and beliefs about the duration of one's asthma predicted intention to adhere in the future (Jessop & Rutter, 2003).

Depression is also an important risk factor for non-adherence. In a meta-analysis, non-adherence was shown to be three times greater in depressed than in non-depressed patients (DiMatteo et al, 2000). The authors of the meta-analysis proposed that this might arise because the sense of hopelessness that typifies depression is likely to influence beliefs about the value of taking medication. Furthermore, people who are depressed often withdraw from those who could provide support, and this in turn may have a negative impact on adherence. The cognitive deterioration which often accompanies depression could also lead to difficulties in adhering to what is often a complex medication regimen.

Discontinuation of medication was examined in 68 patients with RA starting their first DMARD treatment (Wong & Mulherin, 2007). Contrary to the study authors' expectations, discontinuation of the drug within the first year was more likely in older and less anxious patients. Other hypothesised predictor variables, such as depression, relationship with hospital doctors, social support and beliefs about medication did not significantly improve the prediction.

Listening to what a patient really wants will also promote adherence. A principal condition for behaviour change is that one is motivated to change. Self-determination Theory (Ryan & Deci, 2000) emphasizes the importance of keeping therapeutic goals close to the autonomous motivation of people. A behaviour is autonomous when a patient conceives a meaningful rationale for change, values the behaviour, and aligns it with other central values and lifestyle patterns. A common technique aimed at finding motivated behaviour originating from one's own values is motivational interviewing. Another important aspect of autonomy is to work with individualized goals. Therapeutic effects are expected to be better when patients verbalize and strive for their own goals on various domains (i.e., personal care, housekeeping, work/study, hobbies, social, physical activities, and other) and reaching these goals should be rewarding and satisfying. To support intentions to change behaviours and actually fulfil intentions, action plans will help. Action plans detail what specific behaviours will be conducted where, when, and with whom.

6.1. Assessment of Adherence

Adherence can be assessed by several different methods, none of which is without problems. These include pill counts, physiological markers, electronic monitors, and self-report methods. A review concluded that there only slightly higher estimates of adherence were found with self-report than with pill counts (DiMatteo, 2004).

The 19 items Compliance Questionnaire for Rheumatology (CQR, de Klerk et al, 1999) is the only self-report adherence measure created specifically for and validated in rheumatic diseases. A five items version has been found to identify 69 % of low adherers to DMARDS (Hughes et al, 2013). Other self-report measures of medication adherence include the six-item Simplified Medication Adherence Questionnaire (SMAQ; Knobel et al, 2002) and the Brief Medication Questionnaire (BMQ; Svarstad et al, 1999).

6.2 Improving adherence to medication and treatment recommendations

There have been few interventions designed specifically to improve medication adherence in patients with rheumatic diseases (Elliott, 2008). Most interventions have been based on patient education and the teaching of self-management techniques. The effect of group therapy and CBT on medicine adherence is not clear. Those interventions that are effective tend to emphasise developing a daily routine of self-management activities, coping strategies, self-efficacy, and problem solving. It appears that adherence to supervised classes and treatments provided on a one-to-one basis is larger than adherence to home programmes (Kettunen & Kujala, 2004). Research is required to develop evidence-based, pragmatic, patient-centred interventions to improve medication adherence in patients with RA. Practitioners require support and training in the communication of risk and incorporation of patients' beliefs into the consultation process.

7 Daily rheumatology practice

Without doubt, the first task of the rheumatologist is to treat the patient throughout the rheumatic disease process. However, it is important in attempting to achieve overall care for patients that the rheumatologist also has an open mind with respect to the psychosocial aspects of the diseases. The disease process will have psychosocial consequences and psychosocial variables may impact the symptoms and the disease process (Figure 1).

Recognising that patients are experts on their lives and the pressures they have emphasises the importance of listening well to the patient and of assessing whether the patient needs additional psychological care. An educational brochure may help some patients, whereas others will need additional professional help such as CBT or assistance and advice with managing the condition. When patients have a mild form of depressive mood, the motivation to pursue quality-of-life goals may be hampered. The rheumatologist should encourage the patient to pursue these quality-of-life goals and should, during subsequent consultations, check whether the patient was able to pursue them.

Even when the mood or behaviour does not appear to be pathologically disturbed, there may be a psychological impact on the disease process because the patient does not adhere to the prescribed medication or is reluctant to go to the rheumatologist when they have an exacerbation. The mood of the patient may affect pain, physical disability, and the number of tender joints. The physician should be aware that

psychological variables may impact the assessment of disease activity because of subjective judgments of health and tender joints or of commonly used disease activity indices.

Rheumatologists often ask in which way they could help patients with their psychosocial problems. They could help by broadening the consultation to assess more clearly the psychosocial impact of the condition, and by attempting to determine whether their patients need the professional help of a psychologist. It is important, however, to recognise that for all patients the rheumatic disease process is a threat to their psychosocial wellbeing, but that not all of these patients will need professional help. Descriptive, correlational and prospective research has shown the characteristics of patients who are doing relatively well. Moreover, clinical experimental research showed what kind of psychological changes brought about an improved outcome. Based on these sources, advice could be given to the patient, such as the encouragement to think positively.

Exercise is important and long-term adherence can be expected when exercise becomes a pleasurable activity. Second, put effort into achieving quality-of-life goals. Pain hampers quality of life. It is important to perform activities that bring back some joy in life. Third, pursue attainable goals. It is useless to ruminate about activities that are not possible because of the pain or disability. Accomplishing attainable goals may bring back a sense of control. Seize the hour when enjoying the whole day is difficult. Fourth, it is reasonable, and one should expect, to be sad occasionally. It is impossible to be happy all the time. Momentary sadness is understandable and acceptable, but the symptoms of the disease should not lead to chronic sadness and helplessness. Negative, dysfunctional beliefs that hamper the pursuit of these four recommendations should be managed first.

SUMMARY POINTS

- Clinicians should not only attend to the medical/physical dimension but also to the psychosocial and behavioural dimensions of rheumatic diseases for at least four reasons. First, the rheumatic disease process will have an impact on symptoms, well-being, and functioning. Second, physiological (e.g., hormones), psychological (e.g., strategies to cope with problems), and social (e.g., support) variables will also have an impact on symptoms, wellbeing, and function. Third, these physiological, psychological, and social variables may have an impact on the rheumatic disease process. Fourth, comprehensive care of patients necessitates looking beyond the treatment of the disease alone.
- People with rheumatic diseases report a lower quality of life. Physical quality of life is especially severely impaired. Although the impact on mental quality of life is less severe, the prevalence of anxiety and depression is higher than normal.
- Rheumatologists should screen for depression and anxiety in their regular clinical interview by asking whether the patient, during the previous month, has often been bothered by feeling down, depressed or hopeless and by having little interest or pleasure in doing things. What are their worries going forward?

- It is important to know how people feel about their condition and how they cope with it. Associating many symptoms with their condition (illness identity), beliefs in a long duration of illness and in more severe consequences of the disease, as well as a passive way of coping (exerting little control to manage the problem), are associated with worse disease-specific measures of functioning and general role and social functioning. Coping by seeking social support and beliefs in controllability and curability of the disease are related to better functioning.
- The interference of symptoms such as pain and fatigue with activities of daily living is important and in part accounted for by catastrophizing (excessively focusing on symptoms, thinking that something serious might happen, the helpless perception of not being able to cope with the situation), fear of pain, guarding, and control beliefs.
- Pain-related fear and avoidance of physical exercise are essential features of the development of physical disability for a substantial number of patients with musculoskeletal pain. An accumulating number of studies have shown that (graded) physical exercise is an effective means to improve physical function and mental wellbeing.
- Recognition of the role of social factors and social support is important. Social support—receiving emotional and instrumental help from others—is generally found to be beneficial to mental and physical health and it may blunt the harmful impact of stressors of the disease such as pain. Inappropriate and overprotective support is associated with reduced wellbeing and functioning.
- Many brief self-report questionnaires are available to screen patients for disturbances (depression, anxiety) as well as to gain a greater understanding of a patient's cognitions and behaviours. Examples of cognitions are fear avoidance beliefs, attributions about the supposed origin of the disease (somatic or behavioural), beliefs about the prognosis, perceived helplessness, acceptance and benefits and self-efficacy beliefs. Examples of coping behaviour are self-distraction, active coping, behavioural disengagement and expressing emotions.
- Several psychological interventions are available to help patients manage their illness. Patient education leads to improved knowledge and it generally leads to short term improvement of physical and psychological health, whereas long term changes in health status are not convincingly demonstrated. Self-management interventions have been shown to be effective in improving coping strategies and reducing the emotional challenges of the disease. Beneficial effects of self-management interventions on pain, disability, and psychological well-being have been reported over and above effects already obtained with medication. Cognitive-behavioural interventions have been shown to be effective in dealing with other adverse consequences of the disease such as pain and as a long-term treatment against depression. Aerobic and strength exercise is a means to improve physical function and mental well-being. To achieve long-term benefits of physical exercise training, adherence is important, which is better in the case of supervised treatment than in the case of home exercise programmes.
- In daily clinical practice, the patient should be encouraged to enjoy physical exercise, to pursue attainable quality-of-life goals, and to allow one to be sad occasionally. Negative, dysfunctional beliefs that hamper the pursuit of these four recommendations should be assessed and managed first—for example, in self-management interventions or cognitive-behavioural therapy.
- Information, exercise, and cognitive-behavioural treatments combined with appropriate medications may be the most effective treatment approach for patients with rheumatic diseases

IN-DEPTH DISCUSSION I

Provider-patient relations in rheumatology

The doctor-patient relationship is a cornerstone of medical practice. Communication skills are essential in the assessment of symptoms and determining diagnoses. Research over the past twenty years has documented that communication skills have a significant impact on patient satisfaction, adherence to treatment regimes, and health.

1. Lack of concordance between doctor and patient – The importance of the patient perspective

A number of studies have shown a lack of concordance between doctors and patients. In an American study of rheumatology patients, mostly with rheumatoid arthritis (RA), several differences were observed between patients' and physicians' ratings for pain and other health indicators. On average, physicians rated their patients' health status higher than the patients themselves [1].

There are also large variations in the concordance between the actual priorities of the patients and the health care providers' perceptions of what patients find to be important. One study found a relatively high concordance on the significance of pain, but much less concordance regarding the importance to patients of psychological factors [2]. Patients express strong needs to have some control over their disease and life situation. This was rated much more important by patients than most doctors had anticipated.

These findings highlight the importance of understanding the patient's perspective. Several studies have shown that it is important for patients to be considered as persons, not only as carriers of symptoms [3]. Clinicians should include questions on patients' own thoughts, worries, attributions, and priorities in clinical interviews. A number of studies have shown that such questions are often absent in medical consultations, which may be an explanation of the lack of concordance between doctors' and patients' views [e.g. 4].

The inherent invisibility of symptoms such as pain, fatigue, and stiffness challenges the clinician-patient relation and emphasizes the importance of attending to the patient perspective in the consultation, because the provider has to rely on patient self-report to make an appraisal of the severity of symptoms. The lack of objective evidence, uncertainty about symptoms, make it difficult to assess patient's health status in conditions such as, fibromyalgia.

2. Topics may be missed in the consultation

The differences between provider and patient on the understanding of priorities may have as a consequence that certain topics of importance for the patient may be missed in the consultation.

Sensitive topics such as emotional concerns are often only hinted to by patients [5]. In one study of RA patients, less than 20% of patients with moderately severe to severe symptoms of depression spontaneously raised their feelings of depression during their medical visits in a rheumatology clinic and was rarely initiated

by physicians themselves [6]. Similarly, in a study of how RA patients and providers communicated about fatigue the investigators found that while 72% of patients were worried about fatigue, patients more often used implicit cues instead of explicit mention when talking about fatigue. Fatigue was discussed in fewer than half of consultations with physicians, but in 4 of 5 consultations with nurses. In general patients were more satisfied with the nurse specialist's attention to fatigue than with the attention they received from their rheumatologist [7].

3. Premature reassurance

Communicating a positive and optimistic attitude may function well in a medical consultation. But a premature reassurance that all is well is not warranted. In an interview study of patients with rheumatic diseases patients reported that physicians often assured them that the disease was not so severe and that available treatments would be effective. When physicians told RA patients that they had a mild variety of the disease, patients tended to interpret the assurances of the doctor in light of their own understanding of their disease [7]. In general, the assurance from the doctor that the disease was benign lead to uncertainty or anxiety and did not have the intended consequence of providing confidence about the course of the disease. Those patients that had been given the opportunity to disclose their concerns and to be met empathically by the doctor felt the most relieved [8]. Empathic communication, characterized by sensitivity to patient concerns have in several studies been associated with increased patient satisfaction and reduced psychological distress.

4. Involvement of the patient in decisions

There is relatively little research on decision making in rheumatology. Generally, it appears that there is large variation in patients' preferences for taking part in medical decisions. In a study of Japanese RA patients there were significant relationships between active patient participation in the consultation, positive attitude to shared decision making, and a feeling of being understood by the physician [9]. Clinicians should take the opportunity to involve patients in the “negotiations” about treatment options to promote more active patient participation, acceptance, and adherence to recommendations. Patient verbal and nonverbal communications (i.e., pain behaviours, expressions of pain distress, and suffering) are significant sign for the impact of positive and negative reinforcement (i.e., operant learning) on pain. The rheumatologist can use strategies described in Box 1 to in efforts to decrease pain behaviours and increase healthy behaviours such as physical functioning and pacing of activities.

Box 1. Strategies to decrease pain behaviours and increase healthy, adaptive behaviours

- Explanation of pain behaviours, what they communicate, and how they can contribute to increased disability
- Explanation of the development of pain behaviours – the role of attention and responses by significant others to behaviour
- List of Pain Behaviours and Healthy Behaviours

The rheumatologists can explain what pain behaviours are, how they develop, and how they are maintained. He or she can raise the question of how the patients' significant other is aware of their pain, increase in pain, and their distress. Patients can be asked about how their significant others respond to them and how they feel about the responses they receive. Analogies can be used to illustrate the role of reinforcement in maintaining behaviours by using examples of how children or pets learn to engage in various behaviours. .

Box 2. Strategies to eliminate stress-increasing cognitions and to increase adaptive coping

- Explanation of the interaction between stress and pain as circular and vicious
- Explanation of the development of stress- and anxiety-evoking cognitions
- List of stress- and anxiety evoking cognitions in contrast to healthy, stress- and anxiety reducing cognitions
- Protocol of healthy cognitions, emotions and behaviour

Maladaptive cognitions (thoughts and processes) such as catastrophizing (e.g. "I will get more and more disabled and dependent on others", "I can't go on"), helplessness (e.g., "There is nothing I can do to reduce my pain and fatigue"), fear-related cognitions (e.g., "If I am active I may increase may cause damage to my joints and make my pain worse." provoke high levels of affective distress. The rheumatologist can use the cognitive-behavioural approach and explain the vicious cycle of "Stress-Tension-Pain" (see box 2) to help the patient become aware of how their own cognitions and feelings interact and can lead to greater inactivity and isolation. In collaboration with a psychological pain therapist, the rheumatologist can help the patient to create a list with stressful thoughts (e.g., Things I cannot do) and with thoughts for stress relief (e.g. When I breathe quietly, can reduce my feeling of helpless and distress.). Once practiced, the patient can apply that approach to thoughts of helplessness and catastrophizing to replace them by thoughts of active coping (e.g., "When I am relaxed then I can distract myself from pain.", "Despite my RA, there are many things I can still do to enjoy life.") The rheumatologist can make the patient aware to take responsibility of her/his own cognitions aiming on adaptive coping.

Both the operant and the cognitive-behavioural approaches can be used by the rheumatologist to improve communications with the patient, to reduce stress, to increase treatment effectiveness and patient adherence to recommendations by including the patient as a partner in the medical management and self-management of the patient's disease.

Psychosocial aspects of the rheumatic diseases

Dennis C. Turk and Kati Thieme

A previous version was coauthored by Kati Thieme, Rinie Geenen, Arnstein Finset (2014) - Rinie Geenen, Arnstein Finset (2012) - Rinie Geenen, Kathleen Mulligan, Mike Shipley, Stanton Newman (2009)

IN-DEPTH DISCUSSION II

Psychological management of pain

Pain, a common consequence of most rheumatic diseases, the perception of the intensity and impact of pain is determined for each individual by their prior history, current emotional and cognitive state, contextual factors (financial resources, physical environment, and social support) in combination with physical pathology related to the disease itself. When pain persists, psychological processes evolve over the course of the disease and impact physiological processes as well as the adjustment to the disease over time (Figure 1). Thus, it is important to think of chronic diseases longitudinally and there will be changes throughout the course of the disease. The non-pharmacological management of chronic pain as an adjunct to standard pharmacological care is increasingly common. Its contents are listed in Table 1. The targets, outcomes and practice recommendations are discussed.

Figure 1. Factors that contribute to pain. Somatic and psychological inputs affect neural structures that lead to the perception of pain that will have behavioural consequences. The perception of pain involves sensory, affective, and cognitive components (after [19]).

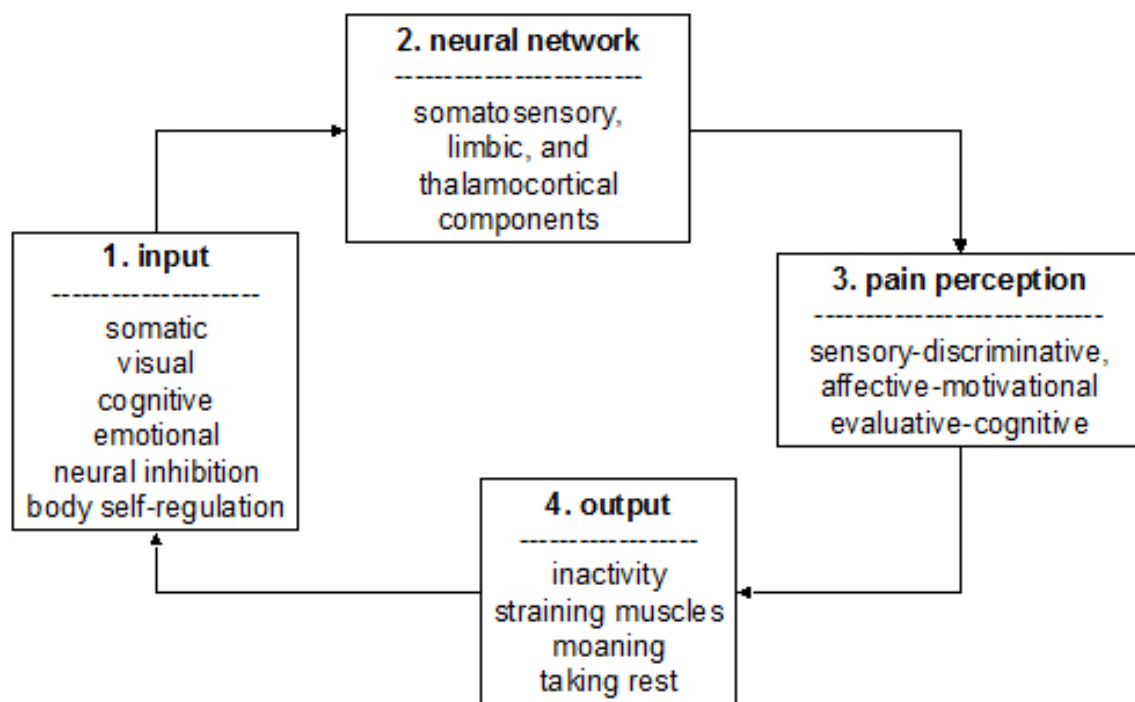

Table 1 Non pharmacological management of pain and its consequences

Patient education refers to any set of planned educational activities designed to reduce pain and its consequences. Education activities directed at the management of pain may involve such varied topics as information about the conditions, encouragement of physical exercise and feasible activities that promote the quality of life, relaxation techniques, physical exercise practices or schemes, the pacing of activities, coping advice, information directed at the importance of social support, decreasing negative, helpless thoughts, and a focus on symptoms, and increase of cognitive symptom management through distraction or guided imagery (e.g., [21]).

Physical exercise training is directed at a gradual build-up of endurance; examples are aerobic exercise training such as indoor or outdoor walking, cycling or aerobic dance, hydrotherapy such as aqua jogging, and strength training (e.g., [3]).

Cognitive behavioural therapy is directed at reduction of pain and physiological responses through the manipulation of maladaptive thoughts, feelings, and behaviour; examples are interventions with one specific aim, e.g., problem-solving, relaxation, stress reduction, or overcoming of fear-avoidance beliefs to support an exercise intervention and, more commonly, the incorporation of various methods, e.g., cognitive restructuring, pain coping skills training, activity pacing, stress management training, relaxation exercises [11, 20].

Education

Education provided to patients about the nature of their disease, treatment options, what to expect, and their responsibilities in self-management are essential to help patients with chronic diseases.

Meta-analyses suggest that on average, educational self-management programs result in a small improvement in pain and disability in rheumatoid arthritis (RA) [14-16]. Meta-analysis of a small number of studies suggests a moderate improvement in these variables in osteoarthritis (OA) [16]. Self-management programs have as yet not been systematically evaluated in fibromyalgia (FM) [3].

A rapidly advancing new feature of education and self-management programs is the use of the internet. This reduces the possibility to systematically evaluate interventions as determining access and outcomes is difficult but it is possible through the Internet to reach many people and for patients to obtain readily available relevant knowledge and in some cases support without much effort or cost.

Physical exercise training

Both inflammation and pain promote inactivity. In the short-term reduction in activity may be reasonable; however, over time reduction in physical activity may lead to physical deconditioning and greater disability. Only a few decades ago, the common recommendation given to patients with chronic inflammatory diseases was to rest. This recommendation has changed dramatically. Nowadays, mild or moderate exercise tailored to the abilities of the patient and severity of the disease is recommended because it leads to better well-being

and functioning. In RA, physical exercise training may improve functional ability without detrimental effects for disease activity, except possibly in patients with considerable joint damage [1].

In FM, mild physical exercise training is recommended as one of the primary interventions [2]. There is growing evidence for positive changes in global well-being, physical function and pain after supervised aerobic exercise training in FM [2-5]. Most sedentary patients with FM are able to manage low-to-moderate-intensity exercise, and positive effects for symptoms and overall functioning have been observed, although high-intensity exercise should be undertaken with care [4].

The increasing number of evaluations that report a positive outcome of such interventions may be due to the lower intensity of the more recent interventions. From a psychological point of view, stopping exercise after an increase in pain (the principle of 'no pain, no gain') results in the concept of 'stopping exercise permanently' being reinforced. It is only, when exercise becomes a pleasurable activity for the patient that long-term adherence can be expected.

High levels of noncompliance with recommendations and drop-out from treatment are common. Possible reasons for drop-out from exercise may include exercise of too high an intensity or too long a duration, too high muscle tension during exercises, an increase of pain on exercise, fear of injury or amplification of pain, and finding repetitive exercise boring. In clinical practice, it is particularly important to attend to the patient's mood and beliefs that may obstruct physical exercise, such as fear of joint or muscle damage or the belief that resting is the best therapy. It is important to listen to and address patients' concerns and make efforts to increase motivation (e.g., persisting with exercise will prevent greater disability; reduction in activity will increase isolation, exercising can actually reduce pain even if initially there may be some increase)

Cognitive-behavioural therapy (CBT)

More severe pain and poorer adjustment to pain have been associated with psychological factors such as catastrophising thoughts, pain-related fear, helplessness, and avoidant coping. In contrast, decreased pain and improved adjustment to pain have been associated with patients' perceived self-efficacy, perception of control, active coping, readiness to change, and acceptance of the chronic disease state [6, 7].

Studies have suggested that cognitive-behavioural interventions may be an adjunctive therapy in the management of rheumatic diseases, but the outcome appears to be dependent on the individual characteristics of the patients. The exact factors involved have not been fully clarified in research.

Meta-analysis of randomised controlled trials in RA showed, on average, a small but significant effect size on pain and functional ability over and above the effects of standard medical care [8-10]. In FM, CBT has not uniformly been shown to be effective [3, 11] but a meta-analysis [12] and a recent intervention [22] suggests that it is on average more effective in reducing symptoms than pharmacological treatment alone.

Individuals differ substantially in their adjustment strategy to pain as well as in their response to treatment. Better results for CBT alone or in combination with physical exercise training are to be expected when interventions are customized to the needs, interests, and abilities of individual patients [7, 11]. A better outcome was observed in patients who on baseline questionnaires were described as 'Dysfunctional', i.e. who had high levels of pain severity, pain interference, psychological distress and lower levels of activity as compared to patients who reported interpersonal problems and patients characterized by an adaptive coping style [13]. Apparently, the CBT that was offered hardly addressed interpersonal problems and provided little room for improving the already adjusted cognitions and behaviour of adaptive copers.

Discussion & the future of pain management

Special attention needs to be paid to the maintenance of what has been learned and to the longer-term integration of exercise and coping into everyday life to maintain improvements after from physical exercise programs and CBT.

In diseases associated with chronic pain, attention needs to be devoted to patients' crucial beliefs and coping strategies that have the capacity to explain the effect on pain of exercise training and cognitive-behavioural interventions. Attention also needs to be directed to the relative intensity of physical exercise that is required in order to reduce pain and improve functioning and well-being.

Prescription

Four simple recommendations for the psychological management of pain could be derived from correlational and clinical experimental research. *First* - Appreciate the importance of exercise. Exercise is important and long-term adherence can be expected when exercise becomes a pleasurable activity. *Second* - *invest time in maintaining and improving quality of life*. Pain hampers quality of life. It is important to perform activities that bring back some joy in life. *Third* - *pursue attainable goals*. It is useless to ruminate about activities that are not possible because of the pain. Accomplishing attainable goals may bring back a sense of control. *Fourth* - *it is allowed to be sad once in a while*. It is impossible to be happy all the time. Momentary sadness is understandable and acceptable but pain need not lead to chronic sadness and helplessness. Negative, dysfunctional beliefs that hamper the pursuit of these four recommendations should be managed first. *Fifth* – Communicate appropriately and openly with health care providers and significant others such as family members. These individuals can be tremendous source of support as you learn to live effectively despite your disease [23].

LEARNING OUTCOMES

- ➔ **Select the most appropriate imaging investigation for assessing a patient with a particular musculoskeletal symptom or rheumatic disease**
- ➔ **Describe and explain the technical aspects of performing different imaging investigations**
- ➔ **Choose the best views, joints to scan and methods of assessment in order to achieve optimum image acquisition and maximal information for a particular purpose**
- ➔ **Compare and contrast the potential strengths and weaknesses of each imaging modality**
- ➔ **Critically evaluate the evidence base for each imaging technique in different musculoskeletal diseases**
- ➔ **Recognise the different pathological manifestations of rheumatic diseases and how these are visualised with the various imaging modalities**

Over the last 15 years, imaging techniques such as ultrasonography (US), magnetic resonance imaging (MRI) computed tomography (CT) but also conventional radiography (CR) have experienced considerable technical improvements. In rheumatology, in particular the advancements within US and MRI have permitted a better understanding of the pathogenesis of several pathologies such as psoriatic arthritis (PsA) and spondyloarthritis (SpA), and better management of rheumatoid arthritis (RA) thanks to their capability to visualize early signs of joint involvement, to objectively monitor the evolution and to predict patient outcome (Baraliakos and Maksymowych, 2016*; Maksymowych and Landewe, 2006; McQueen et al, 2006*; Ostergaard et al, 2008*; D'Agostino et al 2016a*; Ostergaard et al, 2010*; Poggendorf et al, 2011*, D'Agostino et al 2011*, Colebatch et al, 2013*, Mandl et al, 2015*), As compared to CR and CT, US and MRI are not associated with ionising radiation. However, US and MRI are time consuming techniques that require highly trained radiographers and/or radiologists/rheumatologists. To optimise the use of imaging in daily clinical practice it is not only important to consider advantages and disadvantages of the different imaging modalities, but also current evidence for the use of each technique. Furthermore, it is important to remember that prescription of radiologic procedures should always be based on medical history and objective examinations, and with a clear question to the examiner/radiologist, so that the answer can support the most appropriate treatment for the patient.

1 Conventional radiography

CR is a well-established technique and still the first imaging modality performed in patients with musculoskeletal symptoms. Changes in joint and cartilage surfaces, bone pathology, joint space narrowing, subluxation and dislocation can be evaluated with conventional radiography. This modality has a number of advantages. It is available to most physicians and readily accessible to most patients; it is relatively inexpensive; it is generally safe, although it does involve ionising radiation; it provides immediate information that can usually be readily interpreted by the requesting physician to aid diagnosis and management; data are reproducible and can be used for repeated serial evaluation and follow-up. However, this technique does have limitations. It provides a two dimensional picture of three dimensional structures so the plane of assessment is crucial to provide as much information as possible as there may be a danger of missing abnormalities if they are not caught in the plane of the X-ray beam. Thus radiography may be a less sensitive method compared to other tomographical imaging modalities such as CT and MRI. In addition, CR does not provide information on the synovium or other soft tissue structures, which can be critical for the management of patients with inflammatory arthritis.

Radiographic protocols have been established to provide optimal imaging of most joints. These include planes of assessment to maximise diagnostic sensitivity. Several planes are often utilised, typically for hands and feet, an anterior-posterior (figure 1) and lateral or oblique view. Specialist views may also be useful—for example, the 'skyline' view for patello-femoral joint assessment and the 'ball-catchers' view of the hand. Comparison of

bilateral joints can often be informative, and assessment of both hands and feet are useful in the assessment of inflammatory arthritis. Bilateral weight bearing films may be particularly valuable for assessment of joint space narrowing in osteoarthritis (OA) of the knee joint.

Figure 1 Normal posterior-anterior radiographs of the hands and feet. Images courtesy of WA Schmidt.

CR is routinely used in inflammatory as well as degenerative joint diseases. While rheumatoid arthritis (RA) is characterised by bone erosions and joint space narrowing, the radiographic features of the SpA spectrum differ from RA in a number of ways: the spine and sacroiliac joints are more commonly involved, the joint distribution is more likely to be asymmetric, and bone proliferation is frequently present. Degenerative joint diseases such as OA, are characterised by subchondral sclerosis, subchondral cysts and osteophytes. Much of the existing data on the assessment, diagnosis and management of patients with inflammatory arthritis, particularly RA, continue to be based on radiographic findings, and this will be reviewed in greater detail below as will radiographic data with regard to PsA, ankylosing spondylitis (AS) and OA.

1.1 Rheumatoid arthritis

1.1.1 Which joint involvement can be visualised by conventional radiography?

CR remains an important part of the evaluation of patients with peripheral arthritis and initial assessment often includes radiographs of the hands and feet as well as other affected joints. CR can provide important information which may help establish a diagnosis, in addition to determining disease extent, and have a value in prediction of structural progression (ie, progression in chronic bone changes) and long term prognosis. Various pathological abnormalities can be assessed using conventional radiography. These include peri-articular osteopenia (figure 2), joint space narrowing, joint erosions (figures 3 and 4), bone cysts, malalignment, subluxation, dislocation, sclerosis and ankylosis. Evaluation of the soft tissue structures with radiography is limited to describing shadows representing soft tissue swelling which may suggest effusion or

synovitis, but such pathological changes cannot be directly imaged using this technique. Therefore, radiographs are generally better utilised as serial assessments over time to determine any progression of joint damage rather than in the evaluation of initial inflammatory changes in early inflammatory arthritis. Studies have also demonstrated a correlation between joint damage seen on radiographs and disability in longstanding RA, although this link is less strong in patients with early disease (Poggenborg et al, 2011*). It has also been shown that the presence of radiographic erosions relates to disease outcome and confers a worse prognosis (Scott et al, 2000; Goronzy et al, 2004).

Figure 2 Posterior-anterior radiographs of the hands demonstrating widespread periarticular osteopenia in a patient with early inflammatory polyarthritis. Images courtesy of AK Brown.

A variety of joints can be affected by RA and exhibit characteristic features on radiography. These include the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints in the hand, the metatarsophalangeal (MTP) joints in the forefoot, as well as joints in the midfoot and hind foot, the wrist, knees, glenohumeral joint, the elbow and cervical spine.

Soft tissue swelling, periarticular osteopenia and joint space narrowing are often the first radiographic signs of RA (figure 1), although such changes are not specific to this condition. More characteristic changes include bone erosions (figures 3 and 4). Typically erosive changes are located at the bare areas at the margin of the joint (marginal erosions). Often the second and third MCP joints in the hand are affected, particularly on the radial aspect, the ulnar styloid at the wrist and the lateral aspect of the fifth metatarsal head. In chronic cases, erosions become more extensive and often develop more centrally within the joint, resulting in more severe joint space narrowing, which is usually concentric (figure 4), and ultimately subluxation, ankylosis and development of characteristic finger deformities such as ulnar deviation and boutonnière and swan neck deformities. Up to 80% of patients with RA may develop radiographic changes in the cervical spine with the

most important abnormality being atlanto-axial subluxation. This can occur in an anterior, lateral or vertical direction and may be progressive in the setting of uncontrolled inflammation with potentially serious consequences. Alignment can be assessed with anterior-posterior and lateral radiographs of the neck utilising flexion and extension views. Radiographs should usually be performed in a neutral position and forward flexion. If the atlas-dens distance exceeds 3 mm, MRI should be considered to exclude bony destruction, pannus and potential spinal cord or medulla oblongata compression.

1.1.2 Clinical utility

The importance of radiographic changes is supported by the American College of Rheumatology (ACR) which has recommended X-rays as part of the baseline assessment of RA patients (Arnett et al 1988^o). It is also important not to neglect the feet and perform a radiographic assessment of the hands, wrists and feet, as erosive changes may be present in the feet and not in the hands in early disease (McQueen et al, 2006^{*}). In the ACR/European League against Rheumatism (EULAR) 2010 classification criteria, patients who display bone erosions typical for RA plus at least one clinically swollen joint fulfil the criteria and can be classified as RA (Aletaha et al, 2010). Less than half of the patients with early RA have radiographic erosions (Machold et al, 2002), so caution should be applied when interpreting the significance of a normal radiographic assessment in this situation. Up to 30% of patients with RA may not develop radiographic erosions within the first 2 years of disease onset (Ostergaard et al, 2010^{*}). However the converse of this argument is that the majority of patients will have erosions within 2 years of a diagnosis of RA so there is arguably value in conducting radiography. Most experts suggest that radiographs of hands and feet should be performed every 6–12 months in early RA and every 1–2 years in more established disease.

Thus, identification of specific radiographic features, such as erosions, may be useful in the initial assessment of patients with suspected RA, and serial radiographic evaluation in established disease remains one standard by which disease progression, patient outcome and response to treatment may be measured. In addition, radiographs of the atlanto-axial region should be performed, particularly in longstanding and severe RA to exclude destruction and subluxation in this region.

1.1.3 Scoring systems

Several scoring systems have been developed for the evaluation of radiographic changes in RA. These scoring systems allow consistent assessment of joint damage and facilitate accurate measurement of disease severity and progression, and their validity and reliability have been documented. The most widely used systems are the Larsen method and its modifications, which assign to the joints an overall score based on mainly erosive damage by comparison with standard reference films; and the Sharp method and its modifications, which are based on detailed separate assessment of erosions and joint space narrowing in the hands and wrists and, according to the most recent modifications, the forefeet (van der Heijde, 2004). However, the use of such scoring systems is usually confined to research studies, particularly as an outcome measure for response to therapy studies. The complexity of such scoring systems tends to limit their use in routine clinical practice.

1.2 Ankylosing spondylitis and axial spondylarthritis

1.2.1 Which joint involvement can be visualised by conventional radiography?

1.2.1.1 The sacroiliac joints

In AS and axial-SpA, the first radiographic abnormalities are most often seen in the sacroiliac joints. Symmetrical sacroiliitis (figures 5 and 6) is a frequent presenting feature of this condition, and detection of this abnormality with conventional radiography remains part of the diagnostic evaluation of patients with inflammatory back pain and is a key criterion in the classification criteria for AS (see below).

Figure 5 Conventional radiography of sacroiliac joints with sacroiliitis grade 2 bilaterally.

Figure 6 Conventional radiography of sacroiliac joints with sacroiliitis grade 3 bilaterally.

The sacroiliac joints are challenging to image due to their position, anatomy and oblique orientation. An anterior-posterior view is the cornerstone in radiographic imaging of the sacroiliac joint and additional views may be added. The radiographs are often difficult to interpret, due to the irregular anatomy of the joint and projections of overlying structures such as the bowel. This is reflected by reports of significant intra-observer variability in the diagnosis of sacroiliitis on radiographs (Maksymowych and Landewe, 2006*).

The first radiographic finding is usually subchondral bone erosion of the iliac side of the synovial portion of the joint where the cartilage surface tends to be thinner. These erosive changes may progress to give the appearance of a widened joint space. Bone proliferative changes then occur with sclerosis and eventually ankylosis, which is not uncommonly seen early in the disease course. Appearances are typically bilateral and symmetrical in AS. The postero-superior aspect of the sacroiliac is formed by bony apposition and is held together by ligaments which commonly ossify as the disease progresses. These appear as sclerotic change on radiography and commonly obscure underlying structures including the posterior aspect of the joint.

An antero-posterior view of the pelvis may also be useful in the evaluation of patients with suspected spondyloarthropathy. This may reveal similar abnormalities such as erosion and bony proliferation of the cartilaginous pubic symphysis, and possibly changes of enthesopathy at tendon and ligament insertions around the pelvis.

1.2.1.2 The spine

The lumbar, thoracic and cervical spine can also be affected in patients with AS. Radiographs may demonstrate erosive change, ligamentous ossification, and squaring and fusion of the vertebrae (figures 7 and 8). The first changes are usually found at the corners of the vertebral bodies at the thoracolumbar junction in the form of small erosions with adjacent bony repair and proliferation. This produces a 'shiny corner' appearance which is called a Romanus lesion. Periosteal new bone formation along the anterior aspect of the vertebral body may result in 'squaring' of the vertebral body. This may be accompanied by ossification of the outer fibres of the annulus fibrosis of the intervertebral disc and longitudinal ligaments forming syndesmophytes (figure 9). Syndesmophytes are a hallmark of AS and represent vertical bony spurs which may form a bridge between vertebrae, ultimately giving a so-called 'bamboo spine' appearance. In contrast, bony proliferative lesions which tend to be more horizontally oriented are seen in PsA (parasyndesmophytes) and particularly degenerative spine disease (spondylophytes). Ossification of the adjacent paravertebral connective tissue fibres, and in particular the posterior interspinous ligament, may create a solid midline vertical dense line on antero-posterior radiographs in patients with AS. Calcification of the intervertebral discs may also occur. Ossification decreases the mobility of the spine. Low-energy fractures may occur through the ankylosed elements, creating pseudoarthroses typically at the cervico-thoracic and thoraco-lumbar junctions. Spondylodiscitis may also be present. In contrast to bacterial spondylodiscitis, the non-bacterial inflammatory

lesion is characterised by destruction of the vertebral endplate surrounded by well-defined sclerotic areas, reduced height of the disc, and no blurring of contours of the soft tissue.

Figure 7 Conventional radiograph (lateral projection) of the cervical spine. A syndesmophyte is seen at the lower aspect of the anterior vertebral corner of C5 (lower corner).

Figure 8 Conventional radiograph (lateral projection) of the lumbar spine. Syndesmophytes are seen at the anterior vertebral corners of L1 (lower aspect) and L4 (upper aspect).

1.2.1.3 The peripheral joints

The peripheral skeleton may be affected in AS and radiographically detectable changes may occur in the hips, shoulders, knees and MTP joints, and at enthesal sites. Peripheral joint involvement in AS most commonly involves the hips and tends to be bilateral and symmetrical. The hip joint space may be uniformly narrowed, a collar of osteophytes may be seen at the femoral head–neck junction, and axial migration of the femoral head may occur. Up to a third of the patients may develop protrusio acetabuli. The shoulder may be involved in up to 30% of cases and, again, features tend to be bilateral and symmetrical. Typical features include joint space narrowing, erosions, bony proliferation of ligament attachments and the possibility of ultimately ankylosis. In

addition bony spurs may form at the attachment of the plantar fascia at the medial calcaneum and at the insertion of the Achilles tendon.

Figure 9 Cervical spine radiographs demonstrating massive syndesmophyte formation (arrows), almost ankylosis, in two patients with ankylosing spondylitis. (Reproduced with permission from Tan AL, McGonagle D. *Imaging of psoriatic arthritis*. In: Mease PJ, Helliwell PS, eds. *Atlas of psoriatic arthritis*. London: Current Medicine Group, 2005.)

1.2.2 Clinical utility

The New York criteria are, albeit classification criteria, the most commonly used criteria for the diagnosis of AS and are based on clinical features and radiographic sacroiliitis (van der Linden et al, 1984, Ostergaard M et al, 2008*). According to these criteria AS may be diagnosed if grade 2 sacroiliitis (minimal sacroiliitis: loss of definition of the joint margins, minimal sclerosis, joint space narrowing and erosions) or higher occurs bilaterally, or grade 3 (moderate sacroiliitis: definite sclerosis on both sides of the joint, erosions, and loss of joint space) or grade 4 (complete bony ankylosis) occurs unilaterally.

The definitions of radiographic changes according to the New York criteria are included in the Assessment of Spondyloarthritis International Society (ASAS) classification criteria for axial SpA (Rudwaleit et al, 2009a), the European Spondyloarthritis Study Group (ESSG) criteria for SpA (Dougados et al, 1991), and the modified New York criteria (van der Linden et al, 1984).

Radiography of the spine is not included in the classification criteria, but may be useful to follow structural disease progression in patients with spinal involvement. The bone changes seen in patients with axial SpA develop slowly and are often not present in patients with early disease, and generally only minor changes can be observed in 1–2 years.

1.2.3 Scoring systems

Different scoring methods, all based on assessment of lateral views, have been developed to quantify changes in the spine of patients with AS: the Stoke AS Spine Score, Bath AS Radiology Index (BASRI), and the modified Stoke AS Spine Score (mSASSS). A study of the three methods concluded that all measures were reliable but mSASSS was more sensitive to change (van der Heijde, 2004). The spine scores are primarily used in clinical research.

1.3 Psoriatic arthritis

1.3.1 Which joint involvement can be visualised by conventional radiography?

The radiographic changes that may occur in patients with PsA are located at joint and soft tissue structures and comprise osteodestructive as well as osteoproliferative changes: erosions, osteolysis, periostitis, bony proliferation and ankylosis (figure 10), as well as soft tissue swelling and joint space narrowing.

Figure 10 Posterior-anterior radiograph of the hands and wrists in a patient with psoriatic arthritis. Note the 'pencil-in-cup' deformity in the distal interphalangeal joints of the right second and third fingers and the interphalangeal joints of the thumbs. There is also radial subluxation of the distal phalanx of the right thumb. (Reproduced with permission from Tan AL, McGonagle D. Imaging of psoriatic arthritis. In: Mease PJ, Helliwell PS, eds. Atlas of psoriatic arthritis. London: Current Medicine Group, 2005.)

The patterns of joint involvement in PsA are heterogeneous and may include the distal and PIP joints (alone or in combination) or diffuse soft tissue swelling of a digit indicating dactylitis. An RA-like distribution involving the symmetrical small joints of the hands, feet and wrists may occur and may be equally damaging to changes seen in RA (Helliwell et al, 2000). The feet are also commonly affected in PsA. An inflammatory oligoarthritis involving small and/or large joints, particularly ankles, knees and shoulders, may occur. Enthesopathy is often

seen at the acromion, elbow, ischial tuberosity, greater trochanter, patellae, lateral and medial malleolus, and at the attachment of the Achilles tendon and plantar fascia at the calcaneus. Sacroiliitis is also frequently seen (see above).

Radiographs of patients with early PsA may show asymmetric, well defined, marginal erosions. Such early erosions may be indistinguishable from those seen in patients with RA except they may also demonstrate bone proliferation, giving the erosion a slightly spiculated margin. In later progressive disease the characteristic irregular, indistinct erosions and ‘pencil-in-cup’ deformities (a blunt tapered surface of the proximal bone which may protrude into the expanded base of the distal bone of the interphalangeal joints) may be seen (figure 10). In addition, bony proliferation may be observed at entheses—for example, as spurs at the insertion of the plantar fascia and Achilles tendon.

1.3.2 Clinical utility

Several classification systems for PsA have been proposed which have generally been based on different patterns of disease manifestations and not on radiographic findings. However, the European Spondyloarthritis Study Group (ESSG) criteria, in which the presence of radiographic sacroiliitis is an important feature for the diagnosis of axial disease, include radiography of the sacroiliac joints (Dougados et al, 1991). The Classification criteria for Psoriatic Arthritis (CASPAR) criteria from 2006 include radiography of the hands and feet (Taylor et al, 2006). The presence of juxta-articular new bone formation appearing as ill-defined ossification (ie, not a well-defined ossification as in osteophytes) near joint margins is an important feature in the criteria. Up to half of patients with PsA may have evidence of joint damage on radiographs within 2 years of presentation (Kane et al, 2003a). Other changes in early PsA may include dactylitis, periostitis of the bone shaft, and spondylitis. The hand and wrist may be affected in up to three quarters of PsA patients, but the pattern of joint involvement varies from patient to patient and also over time in the individual patient. Spinal involvement may occur in PsA and sacroiliitis may be demonstrable in up to 75% of the patients (Watt 1996). The changes may be more extensive and are more likely to be asymmetrical in PsA and reactive arthritis than in AS.

1.3.3 Scoring systems

Structural joint damage on conventional radiography is an important outcome measure in PsA. Different radiographic scoring methods have been developed, for example, the Sharp/van der Heijde modified scoring method for PsA, which is a detailed scoring system for evaluating erosions and joint space narrowing, while osteolysis and pencil-in-cup phenomena are assessed separately (van der Heijde, 2004). The scoring systems are primarily used in clinical trials.

1.4 Osteoarthritis

1.4.1 Which joint involvement can be visualised by conventional radiography?

Conventional radiography remains the mainstay imaging investigation in the diagnosis and assessment of OA. However, before requesting radiographs, one should consider which joint or joints to image, the plane of assessment, and the questions to be asked of the imaging tool. This will help in selection of the most appropriate radiographic technique. Comparison with previous examinations is invariably useful.

The radiographic features of OA include osteophytes, joint space narrowing, subchondral sclerosis, subchondral cysts, bony remodelling (figure 11), and possibly joint effusions visualised as soft tissue swelling and fat pad displacement. Other arthropathies may co-exist such as calcium pyrophosphate crystal deposition evident as chondrocalcinosis (figure 12). Additional techniques can be employed to yield maximum information. These include weight-bearing films and particular views. For example, weight-bearing radiographs of the knee are essential in order to make the joint space width more representative of cartilage thickness. Other joints such as the hip and ankle maintain good articular contact in a supine position, so weight-bearing films may not be necessary although views of the hip joint may be improved by some internal rotation (eg, 15–20°) and using a standing position. A lateral oblique view of the hip may help to assess posterior-inferior OA. In addition movement and positioning of the joint may be useful. For example, a small amount of flexion of the knee facilitates increased contact of articular surfaces affected by OA. Other techniques such as image magnification, stress films, and systems for digital image analysis may provide additional useful information. Consistent standardised radiographic methodology is crucial for reproducibility of the technique and in particular to facilitate accurate comparison and assessment of severity and progression.

1.4.2 Clinical utility

Conventional radiography is the standard method for the diagnosis and follow-up of OA. However, newer imaging modalities, in particular MRI, are providing additional information which are used in clinical trials and for understanding the disease.

1.4.3 Scoring systems

Various scoring systems have been developed to grade the severity of OA. Among the most well known is the Kellgren and Lawrence five point scale which has been widely used in OA research studies (Plant et al, 1998). Further atlas based scoring systems have been developed which provide more accurate discrimination between individual radiographic features of OA. However, whichever system is used, there may be variable reliability. In addition, quantitative measurement of joint space width as a surrogate for cartilage thickness has been employed in research studies, particularly in cases of knee OA but also in the hip and hand.

Figure 11 Posterior-anterior radiograph of the hands of a patient with osteoarthritis demonstrating soft tissue swelling, joint space loss and osteophyte formation affecting particularly the distal interphalangeal and first carpo-metacarpal joints and particularly the proximal interphalangeal joints of the dominant right hand. 2 Magnetic resonance imaging

MRI allows assessment of all the structures involved in musculoskeletal pathologies, including arthritic diseases, and has been shown to be more sensitive than clinical examination and X-ray for detection of inflammation and damage in inflammatory and degenerative rheumatological disorders. The use of MRI in clinical practice requires considerations regarding safety, availability, cost and duration of examination. MRI is very safe. It involves no ionising radiation or increased risk of malignancies, and adverse effects of the contrast agents are very rare. Disadvantages of MRI include higher costs and lower availability than radiography, longer examination times, and restriction to a limited anatomical area per session..

Preceded by a section on key technical aspects, the characteristics of MRI with respect to diagnosis, monitoring, prognostication and clinical utility in RA, SpA, PsA and OA will be described below.

2.1 Technical aspects

2.1.1 *Peripheral disease*

Whereas MRI examination of axial joints require whole-body MR units, MRI of the peripheral joints can be performed with whole-body MR units or dedicated extremity MR units (E-MRI). Most studies have used whole-body MR units. Low-field E-MRI has been commercially available for some years, increasing the potential for widespread rheumatological use. The advantages of E-MRI compared with whole-body units include markedly lower costs, more comfortable patient positioning and elimination of claustrophobia, a considerable problem in the whole-body units. The disadvantages of E-MRI vary by type of unit, but may include a smaller field of view (ie, smaller anatomical areas are scanned), longer imaging times, and a reduced number of possible imaging techniques compared with the whole-body units. In particular, spectral fat saturation (FS) sequences cannot be acquired due to the low field strength. Some E-MRI units may provide information on synovitis and bone destructions not markedly inferior to what is obtained by standard sequences on high-field units (Taouli et al, 2004; Ejbjerg et al, 2005a), but it should be considered that the performance of different machines may be very different, stressing the need for careful testing before use (Duer-Jensen et al, 2009).

T1 weighted (T1w) imaging sequences are favoured by relatively short imaging times, good anatomical detail, and the ability to visualise the inflamed synovium after intravenous contrast (paramagnetic gadolinium compounds; Gd) injection. Accordingly, pre- and post-Gd T1w imaging has been included in the great majority of studies. Fat and Gd-enhanced tissues have a high signal intensity on T1w images, and as Gd-uptake depends on tissue vascularity and perfusion, the highly vascularised and perfused inflamed synovium is easily recognisable.

T2 weighted (T2w) images depict both fat and fluid/oedematous tissues with a high signal intensity. T2w images are particularly useful when FS techniques, in which the signal from fat is suppressed, are applied. Fat

suppression increases detection of oedematous tissue/fluid located in areas with fatty tissue, for example, bone marrow oedema. On T1w post-Gd images, the use of FS techniques increases the contrast between the inflamed synovium and adjacent structures, but whether it truly gives otherwise unachievable information is questionable. FS requires a homogenous field and a high magnetic field strength, which are not available in low field E-MRI units. The only fat-suppressed sequence possible on low-field E-MRI is the short tau inversion recovery (STIR) technique, which can provide information on bone marrow oedema (Aletaha et al, 2010).

Omitting injection of contrast would decrease imaging times and remove the only invasive element. Unenhanced T1w plus T2w FS/STIR MRI give comparable information on erosions and bone marrow oedema, but is less accurate on synovitis, when compared to Gd-enhanced MRI (Østergaard et al, 2009a). Thus, most authors recommend using Gd-enhanced MRI, if detailed assessment of synovitis is considered important. However, the clinical significance of the fewer details on synovitis presumably achieved with unenhanced imaging has not yet been definitively clarified.

2.1.2 Axial disease

The majority of MRI studies of the sacroiliac joint have used only one imaging plane (semi-coronal, ie, parallel with the axis of the sacral bone). To be maximally sensitive for changes in the ligamentous portion of the sacroiliac joints, imaging in two perpendicular planes is required (Machold et al, 2002). This may therefore be recommended when MRI is used for diagnostic purposes, while it is probably not essential when used as an outcome measure in clinical trials. The majority of MRI studies of the spine in SpA acquire only sagittal images, which are well-suited for assessment of vertebral body changes. However, standard imaging protocols often do not cover the facet, costo-vertebral and costo-transversal joints, due to an insufficient number of sagittal slices. This is crucial, as lesions in pedicles, facet joints, transverse and spinous processes and the posterior soft tissues have been detected in >80% of patients in a SpA cohort (Paulus et al, 1996). The importance of inflammation in the posterior elements in the monitoring and prognostication of SpA remains to be determined.

Bone marrow abnormalities in both sacroiliac joints and spine are detected almost equally well with the STIR and contrast-enhanced T1w FS sequences in patients with SpA (Baraliakos et al, 2005a; Madsen et al, 2010a); the STIR sequence may be better to detect bone marrow oedema in the periphery of fat infiltrations in the sacroiliac joints, whereas small sub-chondral lesions may not be visualised. However, the diagnostic confidence in early SpA may be better if contrast-enhanced MRI is used (Althoff et al, 2009).

For evaluation of structural changes, such as fat infiltrations, bone erosions, sclerosis, and syndesmophytes, T1w semi-coronal images are mandatory. A supplementary T1w FS sequence may improve the evaluation of erosions (Machold et al, 2002), and sequences designed for cartilage evaluation—for example, three dimensional gradient echo sequences—may also be added (Puhakka et al, 2004c).

Thus, recommendations for an adequate MRI of the sacroiliac joint or spine all include at least a T1w sequence without FS and a STIR sequence, in one plane. To which extent further sequences are needed is debated, and may depend on the goal of the examination.

2.2 Rheumatoid arthritis

The majority of MRI studies in RA have investigated knee, wrist and finger joints. While the knee joint is an excellent model joint for methodological studies, the clinical value of MRI is mainly dependent on its power to evaluate wrists, hands and feet, which is also the primary focus of this section. Reports on other peripheral joints are few and not essentially different.

2.2.1 Which joint involvement can be visualised by MRI?

MRI provides multiplanar tomographical imaging with unprecedented soft tissue contrast, without the use of ionising radiation, and allows assessment of all the structures involved in RA—that is, synovial membrane, intra- and extra-articular fluid collections, cartilage, bone, ligaments, tendons and tendon sheaths. MRI and histopathological signs of synovial inflammation are closely correlated (Spoorenberg et al, 2004). MRI can detect synovitis (figure 13), tenosynovitis, bone marrow oedema (figures 14 and 15) and erosions (figure 13) in patients with RA.

Figure 14 Coronal short tau inversion recovery MR image showing bone oedema in the distal part of the second and fourth metacarpal heads. Furthermore, synovitis is seen in the fourth metacarpophalangeal (MCP) joint. The joint to the right is the second MCP joint.

Figure 13 Coronal (A) and axial (B) T1 weighted (T1w) pre-contrast MR images of the second to fourth metacarpophalangeal (MCP) joints show bone erosion in the third and fourth MCP joints, visualised in two planes. (C) The corresponding coronal T1w fat saturated image after contrast injection shows enhancement in second to fourth MCP joints (synovitis) as well as in the third metacarpal head (corresponding to osteitis (bone oedema)).

In a study of MCP joints in patients with early and established RA, mini-arthroscopy confirmed the presence of bone pathology in all joints with MRI bone erosions and histologic and macroscopic synovitis in all joints with MRI synovitis (Ostendorf et al, 2001). MRI bone marrow oedema represents inflammatory infiltrates in the bone marrow—that is, osteitis—as demonstrated by comparison with histological samples obtained at surgery in RA patients (Jimenez-Boj et al, 2007; McQueen et al, 2007). Whereas erosions reflect bone damage that has already occurred, bone marrow oedema appears to represent the link between joint inflammation and bone destruction. A high level of agreement for detection of bone erosions in RA wrists and MCP joints

(concordance at 77–90% of sites) between MRI and CT, the gold standard reference for detection of bony destruction, documents that MRI erosions represent true bone damage (Døhn et al, 2006; Døhn et al, 2008).

Figure 15 Coronal short tau inversion recovery MR image of the wrist joint. Bone oedema is seen in the lunate. The intense bright areas in the capitate and trapezoid bones and the second metacarpal base are bone erosions. These are best visualised on T1 weighted images in two planes (not shown).

2.2.2 Diagnosis

A number of relatively small (≤ 50 patients per study) studies have investigated the differential diagnostic value of MRI, providing ambiguous results; however, recently two large follow-up studies of patients with undifferentiated arthritis have provided better knowledge of the diagnostic utility of MRI to diagnose RA (Tamai et al, 2009; Duer-Jensen et al, 2011). Tamai et al (2009) investigated 129 patients with non-classifiable arthritis despite routine examination, including conventional radiography and biochemical tests, and developed a prediction model containing anti-cyclic citrullinated peptide (anti-CCP) and/or immunoglobulin M rheumatoid factor (IgM-RF), MRI-proven symmetric synovitis, and MRI-proven bone marrow oedema and/or bone erosion. It was found that 71.3% of patients positive for >2 of these variables developed RA within 1 year (specificity 75.9%, sensitivity 68.0%). Presence of bone marrow oedema had a positive predictive value of 86.1% for subsequent development of RA (Tamai et al, 2009). In a study of 116 patients with early undifferentiated arthritis, Duer-Jensen et al (2011) documented that MRI bone marrow oedema in the MTP and wrist joints is an independent predictor of future RA in patients with early undifferentiated arthritis. A prediction model, including clinical hand arthritis, morning stiffness, positive IgM-RF and MRI bone marrow oedema score in MTP and wrist joints correctly identified the development of RA or non-RA in 82% of patients. Thus, two large studies document an independent predictive value of MRI for development of RA.

The ACR/EULAR 2010 criteria for RA (Aletaha et al, 2010) added a role of MRI in the diagnosis of RA. Classification as definite RA is based on the presence of definite clinical synovitis (swelling at clinical

examination) in ≥ 1 joint, absence of an alternative diagnosis that better explains the synovitis, and achievement of a total score ≥ 6 (of a possible 10) from the individual scores in four domains: number/site of involved joints (score range 0–5), serologic abnormality (range 0–3), elevated acute-phase reactants (range 0–1), and symptom-duration (range 0–1) (Aletaha et al, 2010). MRI and US may be used to determine the joint involvement—that is, joint involvement (ie, synovitis) by MRI or US counts in the scoring in the ‘joint involvement domain’ (Aletaha et al, 2010; Østergaard et al, 2010*; Aletaha et al, 2011).

2.2.3 Monitoring disease activity and structural damage

To be valuable for monitoring joint inflammation and destruction, a measure must be reproducible and sensitive to change. MRI allows quantitative (volume of various pathologies or early contrast uptake (‘enhancement’) rate after intravenous injection (only synovitis)) as well as less detailed (qualitative: presence/absence; semiquantitative: scoring) evaluation of synovitis and bone erosions. In observational and randomised clinical trials, semiquantitative scoring has been the most frequently used approach. The Outcome Measures in Rheumatology (OMERACT) Rheumatoid Arthritis MRI Scoring system (RAMRIS) involves semiquantitative assessment of synovitis, bone erosions and bone marrow oedema in RA hands and wrists. This method was developed and validated through iterative multicentre studies under OMERACT and EULAR banners. Consensus MRI definitions of important joint pathologies and a ‘core set’ of basic MRI sequences were also suggested (Rudwaleit et al, 2009b).

The OMERACT erosion scores are closely correlated with erosion volumes estimated by MRI and CT. Good intra- and inter-reader reliability and a high sensitivity to change has been reported, demonstrating that the OMERACT RAMRIS system, after proper training and calibration of readers, is suitable for monitoring joint inflammation and destruction in RA (Østergaard, et al 2003). A EULAR-OMERACT RA MRI reference image atlas has been developed, providing an easy-to-use tool for standardised RAMRIS scoring of MR images for RA activity and damage by comparison with standard reference images (Østergaard et al 2005).

Quantitative methods of synovitis (synovial membrane volumes and post-contrast enhancement rates) are rarely used, but is closely related to histopathological synovitis and sensitive to change (Spoorenberg et al, 2004). Recent software improvements, providing more automated methods, potentially increase assessment speed and reproducibility (Boesen et al, 2009). This encourages revisiting the usefulness of such quantitative methods.

Several studies have demonstrated that MRI is more sensitive than X-ray for monitoring erosive progression in the individual joint regions (McQueen et al, 1999; Østergaard, 1999; Klarlund et al, 2000). RAMRIS scoring of unilateral wrist and MCP joints is more sensitive to change than Sharp/van der Heijde X-ray scoring of bilateral hands, wrist and forefeet (Ejbjerg et al, 2005b).

The superior sensitivity to change and discriminatory ability of MRI compared to X-ray has been demonstrated in randomised controlled clinical trials (RCT) (Quinn et al, 2005; Østergaard et al, 2010*). Quinn et al (2005) demonstrated a significantly lower erosion progression rate by MRI, but not by the Sharp/van der Heijde X-ray method, in 12 methotrexate plus infliximab-treated early RA patients compared to 12 patients receiving methotrexate alone. Recently a large study of 318 methotrexate-naïve patients showed that inhibition of erosive progression of biological therapy compared to placebo can be demonstrated by MRI using half the number of patients and half the follow-up time as by X-ray (Østergaard et al, 2011). A recent review underlines the advantages of using MRI as endpoint in RCT (Peterfy et al 2016*).

2.2.4 Prognostication

Numerous studies have reported the ability of MRI pathology (synovitis, bone erosions or bone marrow oedema) of the wrist and MCP joints to predict radiographic erosive progression. All studies, except two early RA cohorts (Haavardsholm et al, 2008; Hetland et al, 2009), were imaging studies that did not include anti-CCP or take into account other potential prognostic markers such as smoking or shared epitope carriage. Haavardsholm et al (2008) reported bone marrow oedema and male gender (but not anti-CCP) to be independent predictors of radiographic progression after 1 year in a single-centre cohort of 84 patients treated according to standard clinical practice. A study by Hetland et al (2009) was the first clinical trial with a standardised treatment protocol that investigated the predictive value of a variety of potential prognostic markers including both imaging (MRI and conventional X-ray), immunologic (anti-CCP, IgM-RF and IgA-RF), environmental (smoking, educational level), genetic (shared epitope), and disease activity markers (Hetland et al, 2009). The main finding was that MRI bone marrow oedema at presentation was the strongest predictor of radiographic progression 2 years later in early RA patients. Three-year and 5-year follow-up, respectively, in the two retrospective cohorts have documented that MRI-bone marrow oedema is also a predictor of long term radiographic progression (Heltand et al, 2010; Bøyesen et al, 2011a).

A relation between baseline MRI findings and long term functional disability has only been documented in one study (Battistone et al, 1999). Furthermore, a high baseline MRI tendinopathy score was predictive of tendon rupture at 6 years (odds ratio 1.52) (McQueen et al, 2005).

Another issue of high clinical importance is whether MRI is useful in patients in clinical remission, to predict the disease course. Brown and co-workers reported that MRI and US synovitis is frequent in patients in clinical remission, and that baseline US synovial hypertrophy, US power Doppler (PD) signal and MRI synovitis scores in individual joints were significantly related with progressive radiographic damage at 1-year follow-up (Van Der Heijde et al, 2005). The study encourages further exploration of MRI and US for predicting the disease course and for evaluating disease status, including defining remission.

2.2.5 Summary/clinical utility

MRI can be used to visualise all structures involved in RA. Two large studies document an independent predictive value of MRI for the development of RA, implying a diagnostic utility when used in combination with clinical parameters. Furthermore, MRI and US have an important role in the ACR/EULAR 2010 criteria for RA, as it can be used to count involved joints. MRI can be used for sensitive monitoring of disease activity and damage and, as bone marrow oedema is a strong independent predictor of radiographic progression, for stratification into good- and poor-prognosis patients.

2.3 Ankylosing spondylitis/axial spondyloarthritis

MRI allows direct visualisation of the abnormalities in peripheral and axial joints and entheses that occur in AS, PsA and other forms of SpA. AS, which is thought to be the most common and most typical form of SpA, is dominated by axial disease manifestations in the spine and sacroiliac joints, and clinical assessment systems have focused on assessing axial disease. In accordance with this, this section will mainly focus on the axial manifestations, while the PsA section below will deal with peripheral manifestations.

2.3.1 Which joint involvement is visualised by MRI?

MRI, through its ability to detect inflammatory changes in bone and soft tissues, is the most sensitive imaging modality for recognising early spine and sacroiliac joint changes in AS/ axial SpA. MRI findings indicating active disease in the sacroiliac joints (sacroiliitis) include juxta-articular bone marrow oedema and enhancement of the bone marrow and the joint space after contrast agent administration (figure 16), while visible structural changes include bone erosions, sclerosis, periarticular fatty tissue accumulation, bone spurs (such as syndesmophytes), and ankylosis (figure 17). Typical lesions of the spine, which indicate active disease, are spondylitis, spondylodiscitis, and arthritis of the facet, costovertebral and costo-transverse joints (figure 18). Structural changes, such as bone erosions, focal fat infiltration, bone spurs and/or ankylosis, frequently occur. Enthesitis is also common, and may affect the interspinal and supraspinal ligaments and the interosseous ligaments in the retro-articular space of the sacroiliac joints. Some patients also have disease manifestations in peripheral joints and entheses, and these can be visualised by MRI as in other diseases (Hermann et al, 2004a; Maksymowych and Landewe, 2006*).

Figure 16 Semicoronal short tau inversion recovery (A) and T1 weighted (T1w) (B) MR images of a patient with axial spondyloarthritis, showing bone marrow oedema at both sacroiliac joints, being most pronounced in the right sacral and iliac bones, documenting active sacroiliitis. (B) Corresponding T1w MR image shows fat infiltration and bone erosion.

Figure 17 Semicoronal T1 weighted MR images of the sacroiliac joints of a patient with ankylosing spondylitis. (A) Sacral and iliac erosions primarily in the left sacroiliac joint. (B) Sacral fat infiltrations in the both sacroiliac joints located in the sacral bone.

Figure 18 Sagittal short tau inversion recovery image of the lumbar and lower thoracic spine showing bone marrow oedema at the anterior vertebral corners of Th4, Th5, Th6, Th7 and Th9.

2.3.2 Diagnosis

The introduction of MRI has resulted in a major improvement in the evaluation and management of patients with SpA. In particular, MRI makes it possible to diagnose patients earlier in the disease course (Rudwaleit et al, 2009a). Diagnosis was previously dependent on the presence of bilateral moderate or unilateral severe radiographic sacroiliitis, as part of the modified New York criteria for AS. This frequently delayed the diagnosis by 7–10 years (Taouli et al, 2004). Now, through the recent ASAS classification criteria for axial SpA, MRI forms an integral part, as patients with active sacroiliitis on MRI plus one clinical feature (eg, psoriasis, enthesitis or uveitis) should be classified as having axial SpA (Rudwaleit et al, 2009a). A consensus-based definition has been made of the requirements to constitute active sacroiliitis—that is, to fulfil the MRI criterion of the ASAS

criteria ('a positive MRI') (Rudwaleit et al, 2009b). Only bone marrow oedema, located in ≥ 2 sites and/or in ≥ 2 slices, counts.

Recent data demonstrate that incorporating structural damage lesions (erosions) into the criteria would improve the diagnostic utility of MRI (Weber et al, 2010a; Weber et al, 2010b). However, in January 2011 ASAS decided to await further data before revision of the definition of a positive MRI in the axial SpA criteria could be reconsidered.

2.3.3 Monitoring disease activity and damage

MRI can provide objective evidence of currently active inflammation in patients with SpA (Hermann et al, 2004a; Maksymowych and Landewe, 2006, Baraliakos and Maksymowych, 2016*). Until the introduction of MRI, disease activity assessment was restricted to patient-reported outcomes, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and Functional Index (BASFI), because disease activity could not be assessed in a sensitive manner by biochemical (mainly C-reactive protein (CRP) or erythrocyte sedimentation reaction) or physical evaluation.

Several scoring systems for assessment of disease activity in the sacroiliac joints and in the spine have been proposed (for details, see recent review by Ostergaard et al 2010*). Generally, MRI disease activity assessments have mostly focused on the spine.

Three main scoring approaches of activity in the sacroiliac joints have been proposed, based on either global scores per quadrant or individual scores in consecutive semi-coronal images through the joint (Hermann et al, 2004b; Puhakka et al, 2004a; Maksymowych et al, 2005b; Madsen et al, 2010a). The presence and extent of bone marrow oedema in the cartilaginous portion of the joint is the primary MRI feature that is scored. In an OMERACT-ASAS multi-reader exercise, agreement between readers and sensitivity to change were compared and found to be somewhat better for the most detailed scoring method (the Spondyloarthritis Research Consortium of Canada (SPARCC) method) (Lukas et al, 2007). A recent method also scores the ligamentous portion of the joint (Machold et al, 2002). Whether this system's ability to visualise inflammation in all aspects of the joint (comprehensiveness) outweighs the disadvantages of higher complexity and longer acquisition and reading time remains to be determined, as does the sensitivity to change.

Several scoring systems for assessment of disease activity in the spine have been proposed (Braun et al, 2003; Maksymowych et al, 2005a; Haibel et al, 2006; Lambert et al, 2009; Madsen et al, 2010b). While the two most recent scoring systems (Lambert et al, 2009; Madsen et al, 2010) have not yet been fully validated, the sensitivity to change and discriminatory ability of the three most used systems—the Ankylosing Spondylitis spine Magnetic Resonance Imaging-activity (ASspiMRI-a) score, grading activity 0–6 per vertebral unit in 23 units; the Berlin modification of the ASspiMRI-a score, grading activity 0–3 per vertebral unit in 23 units; and

the SPARCC scoring system (Braun et al, 2003; Maksymowych et al, 2005a; Haibel et al, 2006)—have been demonstrated in clinical trials, and they have been tested against each other by the ASAS/OMERACT MRI in AS group (Lukas et al, 2007). All methods were feasible, reliable, sensitive to change and discriminative. The SPARCC method had the highest sensitivity to change, as judged by Guyatt's effect size, and the highest reliability as judged by the inter-reader intra-class correlation coefficient (ICC) (Lukas et al, 2007).

Other scoring systems include a combined score of sacroiliac joints and the lower part of the spine (Marzo-Ortega et al, 2001; Marzo-Ortega et al, 2005) and two recent systems (Lambert et al, 2009; Østergaard et al, 2009b); both have individual components for assessment of inflammatory and structural lesions. A Canada–Denmark system provides a detailed anatomy-based set of definitions plus an assessment system for active inflammatory lesions, which was particularly designed to study the temporal and spatial patterns of inflammation, and their relation to the development of structural damage on MRI and radiography (Lambert et al, 2009; Østergaard et al, 2009b).

MRI is much less established for the assessment of structural changes than inflammatory changes. Scoring methods assess erosions, sclerosis, fat deposition and/or bone bridges separately or as global score are under development (Maksymowych et al 2015a; Weber et al 2015).

Until recently, the only systematic evaluation method of structural changes proposed for evaluation of the AS spine was the Ankylosing Spondylitis spine Magnetic Resonance Imaging-chronicity (ASspiMRI-c) scoring system, in which each discovertebral unit is assigned a score from 0 to 6 based on an overall assessment of sclerosis, squaring of vertebrae, syndesmophytes and ankylosis (Braun et al, 2003).

Unfortunately, the reliability of the ASspiMRI-c score has been shown to be poor and in a comparative study this MRI system was not superior to radiography for detection of new bone formation (Braun et al, 2003; Braun et al, 2004). However, no specific definitions for syndesmophytes and ankylosis seen on MRI were proposed and it was not clear whether the poor reliability was due to unreliable detection of all or only some lesions, since data were only reported for the score as a whole. Two new systems (Østergaard et al, 2009b; Madsen et al, 2010b) score the individual features separately. Further studies are needed to elucidate the validity and clinical utility of these systems.

2.3.4 Prognostication

Three spine studies have documented an association between the presence of bone marrow oedema at anterior vertebral corners on MRI and subsequent development of syndesmophytes at the same vertebral corners on radiography after 2 years of follow-up. Presence as opposed to absence of MRI inflammation provides risks of a new anterior radiographic syndesmophyte at the level of 6.5% versus 2.1% (Baraliakos et al, 2008), 20% versus 6.3% (Maksymowych et al, 2009), and 15.6–16.7% versus 2.2–3.2% (Pedersen et al, 2009),

respectively. In two studies, the association was even more pronounced in those vertebral corners in which the inflammation had resolved following institution of anti-tumour necrosis factor (ant-TNF) therapy, possibly explained by TNF α in active inflammatory lesions inhibiting formation of new bone (through an upregulation of Dickkopf-1, a negative regulator of bone formation), whereas reduction of TNF by applying a TNF-antagonist therapy allows tissue repair to manifest as new bone (Maksymowych et al, 2009a; Pedersen et al, 2011).

One study suggests that inflammatory back pain in patients with early disease, severe sacroiliac MRI bone marrow oedema together with HLA-B27 positivity is a strong predictor of future AS, according to the modified New York criteria (likelihood ratio 8.0), whereas mild or no sacroiliitis, irrespective of HLA-B27 status, is a predictor of not developing AS (Bennett et al, 2008). Data on the value of MRI for predicting therapeutic response in SpA are very limited. A high spine MRI score (Berlin method) and short disease duration have been reported as statistically significant predictors of a BASDAI improvement of >50% (BASDAI50) in AS patients receiving a TNF-antagonist (Rudwaleit et al, 2008). Further and larger studies are needed to clarify the role of MRI in the prediction of therapeutic response.

2.3.5 Summary/clinical utility

MRI has a very important clinical role in the diagnosis of early SpA, and it is a part of the recent ASAS classification criteria for axial SpA. MRI allows sensitive and reproducible monitoring of axial inflammation and is frequently used for this purpose in clinical trials. Certain MRI findings have predictive value for subsequent development of syndesmophytes. However, further studies are needed to determine the optimal use of MRI for monitoring and prognosticating SpA in clinical practice.

2.4 Psoriatic arthritis

The clinical appearance of PsA is very diverse, involving the spine, sacroiliac joints, peripheral joints and/or entheses; accordingly MRI findings vary. PsA shares clinical manifestations with RA and SpA and this also applies to its MRI features (McQueen et al, 2006*). Peripheral PsA synovitis appears similar to RA synovitis on MRI. Similarly, PsA bone erosions do not have disease-specific MRI features, and MRI bone marrow oedema can involve any bone. As in other spondyloarthritides, enthesitis, dactylitis and spondylitis can be seen. Enthesitis may occur adjacent to peripheral and axial joints, and is often associated with synovitis and sometimes with bone marrow oedema (McQueen et al, 2006*). Dactylitis has been shown on MRI to be due to tenosynovitis with effusion, and is sometimes associated with diffuse soft tissue oedema and/or synovitis in nearby finger or toe joints (Olivieri et al, 1997; Olivieri et al, 2002). There are few MRI studies in axial PsA, but findings are similar to AS findings, although more frequently asymmetric (Bollow et al, 2000; Williamson et al, 2004).

2.4.1 Which joint involvement can be visualised by MRI?

MRI can visualise both peripheral and axial musculoskeletal anatomy and PsA disease manifestations. Findings include synovitis (figure 19), tenosynovitis (figure 20), periarticular inflammation (figure 20), enthesitis, bone marrow oedema, bone erosion (figure 21), and bone proliferation (figure 21) (Totterman, 2004; Eshed et al, 2007; Østergaard et al, 2009c).

Figure 19 T1w fat suppressed MR images of the metacarpophalangeal (MCP) joints of a patient with psoriatic arthritis before (A) and after (B–C) injection of gadolinium. Contrast enhancement after contrast injection (synovitis) is particularly seen in the fourth MCP joint, but also in the second MCP joint. The orange line on the coronal slice (C) illustrates the localisation of the axial slices (A–B). Images courtesy of C Wiell.

Figure 20 T1 weighted MR images of the fingers of a patient with psoriatic arthritis before (A) and after (B) injection of gadolinium. Axial (A, B) and coronal images show flexor tenosynovitis in the second, fourth and fifth finger and subcutaneous oedema (periarticular inflammation) of the second finger. Images courtesy of C Wiell.

Figure 21 Axial and coronal T1 weighted MR images of the fingers in a patient with psoriatic arthritis. Bone erosion and new bone formation are found in the second and third metacarpophalangeal joint. Image courtesy of C Wiell.

The entheses have attracted attention as a possible primary location of disease in patients with PsA (Maksymowych et al, 2010). Nail disease is common in PsA, and distal interphalangeal joint (DIP) joint inflammation on MRI has been described to extend to the nail bed (Tan et al, 2007). It has been suggested that onychopathy precedes DIP joint damage in PsA, and that MRI of nails is of diagnostic value in undifferentiated SpA (Soscia et al, 2005).

PsA can be clinically silent. In patients with psoriasis without arthritic signs or symptoms, pathological findings on MRI (including periarticular oedema, tendon sheath effusion, intra-articular effusion, synovial pannus, bone erosion, bone cysts, subchondral changes, and joint (sub)luxation) have been reported in >2/3 (68–92%) versus none to ≤1/12 of healthy controls (Offidani et al, 1998; Erdem et al, 2008; Emad et al, 2010).

A general agreement on which joints to image to assess PsA disease activity and damage is not established, and possibly needs to be individualised, based on the disease pattern. It is generally suggested that T1w sequences are in two planes, supplemented by a T2w fat-suppressed or STIR sequence, preferably also in two planes. Intravenous contrast injection is optimal for assessment of synovitis and tenosynovitis, but can be omitted if the aim is purely to detect bone marrow oedema, bone erosion and/or bone proliferation (Madsen et al, 2010c).

2.4.2 Diagnosis

As described above, MRI can detect the different pathologies involved in PsA. However, no studies have documented that MRI in an early undifferentiated arthritis cohort can be used to differentiate PsA from other arthritides.

2.4.3 Monitoring

Most studies only report qualitative MRI assessments of the different pathologies of PsA (see McQueen et al (2006)* for summary up to 2005). Quantitative assessment of contrast enhancement has been reported (Antoni et al, 2002; Cimmino et al, 2005), but is insufficiently validated for clinical use.

Different scoring systems for bone marrow oedema, erosions and/or synovitis in patients with PsA have been developed (Tehranzadeh et al, 2008; Anandarajah et al, 2010), but these have only been used in a few patients and not by centres other than the ones that developed them. To be able to compare the results of different MRI studies of PsA, it is of major importance to have a standardised system for scoring the pathologies. The international OMERACT MRI in inflammatory arthritis group has developed the OMERACT Psoriatic Arthritis Magnetic Resonance Image Scoring System (PsAMRIS) for evaluation of inflammatory and destructive changes in PsA hands (McQueen et al, 2009; Østergaard et al, 2009c; Bøyesen et al, 2011b). This method has shown good intra- and inter-reader reliability and, for inflammatory features (synovitis, tenosynovitis, periarticular inflammation), also good sensitivity to change. In a randomised controlled trial the reductions in synovitis and

oedema were larger in patients treated with abatacept than placebo (Althoff et al, 2009, Glinatsi et al 2015). The usefulness of the OMERACT PsAMRIS in clinical trials and practice needs further testing in clinical trials.

2.4.4 Prognostication

In contrast to RA, no longitudinal studies of the prognostic value of MRI findings in PsA are available. In a cross-sectional MRI study of 11 patients with the aggressive arthritis mutilans form of PsA, and 17 patients with non-mutilating PsA (erosive PsA without bony lysis), there was a close relation between presence of erosion and bone marrow oedema. Based on this, the authors suggest that MRI bone marrow oedema in PsA is also a 'forerunner' of structural joint damage (Tan et al, 2009). Further longitudinal studies are needed to clarify this.

2.4.5 Summary/clinical utility

MRI can be used to visualise all structures involved in PsA, and a system for monitoring of disease activity and damage has been developed. The value of MRI for diagnosis, monitoring of disease activity, and prognostication needs to be established.

2.5 Osteoarthritis

Based on the tomographic nature and ability to visualise cartilage, bone and various soft tissues, MRI is very well-suited for assessment of inflammatory changes, and structural and compositional changes in the cartilage and other structural lesions in OA. The majority of studies have been undertaken in knee joints, or less frequently hip joints, but recent findings in small joints in the hand in generalised OA have also attracted attention.

2.5.1 Which joint involvement can be visualised by MRI?

MRI allows direct assessment of the thickness, surface contour, and internal architecture of articular cartilage in OA (Gray et al, 2004; Eckstein et al, 2007; Guermazi et al, 2008), making staging and monitoring of OA development possible. Osteophytes at the joint margins or beneath the articular cartilage may be seen. Subchondral changes include bone marrow oedema, sclerosis, and bone cysts. MRI 'bone marrow lesions' (or bone oedema lesions), which are areas with inhomogeneous, intermediate-low signal on T1w and high signal on water sensitive techniques (STIR/T2FS), have, by comparison with histological samples obtained by surgery in advanced OA, shown trabecular micro-fracture and bone marrow fibrosis and/or necrosis, but limited interstitial oedema (Bergman et al, 1994; Zanetti et al, 2000; Saadat et al, 2008; Taljanovic et al, 2008). Cystic changes may occur within the areas of subchondral sclerosis and produce well-defined lesions, with high signal on STIR/T2FS. Synovitis is seen frequently by MRI in OA, albeit to a lesser degree than in RA (Østergaard et al,

1997). Synovitis scores obtained by contrast-enhanced MRI have demonstrated a good correlation with arthroscopic and microscopic synovitis scores (Loeuille et al, 2009).

2.5.2 Diagnosis

The use of MRI in the diagnosis of OA offers the advantages described above—that is, that MRI can sensitively depict all the involved pathological changes.

2.5.3 Monitoring

Various quantitative and semi-quantitative techniques have been used to measure structural abnormalities and changes on MRI in OA (Guermazi et al, 2008). Quantitative measurements apply computer-aided image processing to quantify various aspects—for example, volumes of cartilage, bone volume, bone marrow lesion volume, menisci or synovium. Measures of cartilage composition are also available—for example, quantification of glycosaminoglycan content (Gray et al, 2004; Eckstein et al, 2007). Semi-quantitative methods have been used to provide semi-quantitative ‘multiple feature’ (‘whole-organ’) assessments in the knee, based on conventional MRI acquisitions (Biswal et al, 2002; Peterfy et al, 2004; Kornaat et al, 2005; Hunter et al, 2008). These features include articular cartilage morphology, sub-articular bone marrow abnormality, bone cysts, sub-articular bone attrition, marginal and central osteophytes, medial and lateral meniscal integrity, anterior and posterior cruciate ligament integrity, medial and lateral collateral ligament integrity, synovitis/effusion, intra-articular loose bodies, and periarticular cysts/bursitis (Hunter et al, 2011).

Available data, as reported in a recent systematic literature review, indicate that quantitative measures of joint structure have excellent reliability (ICCs >0.80), and the agreement for semi-quantitative measures was also good-excellent (kappa 0.52–0.88) (Hunter et al, 2011). Furthermore the responsiveness data showed a potential benefit of MRI compared to conventional radiography that generally has standardised response means (SRMs) in the 0.3–0.4 range (Emrani et al, 2008), while certain MRI measures had SRMs >0.80. Multi-feature assessment of the knee by semi-quantitative scoring methods showed a responsiveness of cartilage assessment comparable with quantitative methods (Biswal et al, 2002; Peterfy et al, 2004; Kornaat et al, 2005; Hunter et al, 2008). SRMs for semi-quantitative assessments of medial tibiofemoral cartilage morphology, synovium and bone marrow lesions of 0.55, 0.52 and 0.43, respectively, have been reported (Hunter et al, 2011).

2.5.4 Prognostication

In a recent systematic literature review, the value of MRI to predict certain outcomes in OA was explored, focusing on the ability to predict total knee replacement surgery, change in symptoms, radiographic progression as well as MRI progression (Hunter et al, 2011). It was reported that quantitative cartilage volume change and presence of cartilage defects or bone marrow lesions in all studies was significantly related to

subsequent total knee replacement—that is, a predictive value was demonstrated (Cicuttini et al, 2004; Wluka et al, 2005; Scher et al, 2008).

Furthermore, bone marrow lesions have been moderately related to symptom onset and increased pain in a 15-month follow-up study (Felson et al, 2007). An increase in bone marrow lesion volume was observed in 49.1% of patients with painful knee OA as opposed to only 26.8% of OA patients without knee pain. Among patients with no bone marrow lesions at baseline, the development of new bone marrow lesions were more common in painful knees than in control knees (32.4% vs 10.8%) (Felson et al, 2007). A recent knee OA case–control study showed that changes in bone marrow lesion extent was associated with fluctuations in knee pain, and improvement of bone marrow lesions, but not of synovitis or effusion, was associated with a decreased risk of knee pain (Østergaard, 1999). In contrast, the systematic literature review showed an inconsistent and generally weak relation between cartilage loss and symptom change, and a weak relation between change in synovitis and change in pain. Finally, the review indicated that the presence of meniscal damage, cartilage defects and/or bone marrow lesions predicts subsequent MRI progression.

2.5.5 Summary/clinical utility

MRI can be used to visualise all structures involved in OA, and several reproducible and responsive quantitative and semiquantitative methods for monitoring of disease progression have been established. These include both systems for pure cartilage assessment and ‘whole-organ’ assessment systems, incorporating aspects of synovitis, bone marrow lesions, etc. A prognostic value of certain MRI features, particularly bone marrow oedema, for disease progression has been established. Availability of effective therapies, and the ensuing increased need for sensitive diagnosis, monitoring and prognostication, would increase the clinical benefit of using MRI in OA clinical practice.

3 Computed tomography

CT enables high resolution imaging in multiple planes, although it requires exposure to ionising radiation. Multislice CT offers advantages over conventional CT with improved scan resolution, shorter imaging time and a lower radiation exposure (Ostendorf et al, 2001). CT is especially useful for visualising bone and cartilage, so it has been applied to the study of pathologic changes in these structures including subtle cortical or intraosseous lesions. However, unlike US and MRI, it is unable to visualise other joint and soft tissue structures with discernible clarity so it is not able to clearly demonstrate changes such as inflammation or infection.

In the evaluation of bone erosions in RA, the first comparison study between imaging modalities suggested that CT may be more sensitive than radiography but inferior to US and MRI in the detection of erosions of the humeral head, although it was commented that MRI may overestimate erosion size (McQueen et al, 2007).

Some authors regard CT as the gold standard for the assessment of destruction of calcified tissue, such as bone erosions in RA (Dohn et al, 2007; Dohn et al, 2008).

3.1 Rheumatoid arthritis

Using CT as the reference method, Døhn et al demonstrated high specificities for MRI (96%) and US detected erosions (91%) in RA MCP joints. Radiography exhibited high specificity (100%) but low sensitivity (19%). CT detected more erosions than the other imaging modalities (Døhn et al, 2006). A study comparing CT and MRI, to determine erosion volumes in the MCP joints of RA patients, demonstrated very high intra-modality and inter-modality agreements (Dohn et al, 2007). The use of micro CT in RA and PsA patients seems to permit a better visualization of erosive changes and proliferation with possible implication in term of diagnosis, follow up or prognosis (Barnabe et al, 2015; Albrecht et al 2013; Finzel et al 2011; Simon et al 2016). However this technique is actually used predominantly for research and not for clinical management. There may also be a role for CT in the imaging of patients with crystal arthropathies such as gout with evidence to suggest that CT may provide more specific detection of tophi than US or MRI (Jimenez-Boj et al, 2007, Araujo et al 2015; Bayat et al. 2016). In general, the use of CT in the evaluation of patients with early inflammatory arthritis is limited, as better validated, more sensitive tools not requiring radiation or contrast exposure are currently available, such as US and MRI.

3.2 Axial spondyloarthritis

The demonstration of sacroiliitis is important in the diagnosis of AS, but this can be difficult to detect clinically and radiographs may be normal especially in early disease. CT may be useful to assess such patients as this technique is often able to depict sacroiliitis before it is apparent on radiography (figure 22). CT has also been compared to MRI in imaging sacroiliitis. While some studies have found the two techniques to be comparable, MRI has the advantage of being able to image subchondral bone oedema, an early marker of active sacroiliitis (Yu et al, 1998; Puhakka et al, 2003), and is therefore the imaging modality of choice in such cases. However, CT is well suited for exact delineation of structural bone changes, including fractures, and is of value for resolving particular clinical problems, or for diagnosing early the presence of a definite radiographic sacroiliitis in patients with suspected SpA (Devauchelle et al, 2009). Another potential use of CT is the detection of insufficiency fractures of the pelvis and sacrum. Such patients may exhibit indeterminate clinical symptoms and signs and radiography may be normal. Isotope bone scanning and MRI can be used in such circumstances but CT may be able to provide more accurate visualisation of a fracture.

4 Ultrasonography

US is an imaging technique based on the emission and reception of mechanical sound waves by piezoelectric crystals located inside the transducer or probe. The frequency is greater than the hearing frequency range of the human ear (ie, 20 kilohertz (kHz)). Ultrasound wave frequencies of diagnostic US systems range from 3 to 25 megahertz (MHz). Ultrasound waves transmit differently through different media depending on their composition and are reflected at the interfaces between materials of different acoustic impedance. The reflection of ultrasound through the body tissues generates US images that consist of varying degrees of black-and-white images. The US technique includes grey scale (GS) imaging of anatomic structures and blood flow detection by Doppler technique. Doppler US is based on the alteration of the frequency of a sound beam reflected back to the source when it encounters a moving object.

For the last 50 years, the medical applications of Doppler US have included diagnosis of abdominal, pelvic, obstetric, breast and cardiac pathologies. More recently, musculoskeletal ultrasonography (MSUS) has progressively become an established imaging technique for evaluating periarticular and intra-articular structures involved in musculoskeletal conditions, including rheumatic diseases. The use of high-resolution transducers improves the visualisation of different anatomic structures (figure 23) and permits the assessment of a wide range of inflammatory and structural abnormalities (figures 24–27). The use of appropriate probe frequencies is mandatory for the correct imaging of musculoskeletal structures and optimises the US detection of local pathology. At higher frequencies, the image resolution is greater but the tissue penetration is lower. Therefore, higher frequency linear transducers (eg, 10–18 MHz) should be used for superficial anatomic

structures, such as the small joints of the hand and feet, whereas lower frequency transducers (eg, 5–10 MHz) are appropriate for deeper joints, such as the hip, ankle and shoulder. In addition, a correct machine setting markedly increases the sensitivity of the equipment in assessing a number of abnormalities, both by using GS and Doppler modalities.

Figure 23 *Ultrasonography of the third metacarpophalangeal joint of a normal subject demonstrating joint and soft tissue structures.*

Figure 24 *Ultrasonography (grey scale and power Doppler) demonstrating synovial hypertrophy of the third metacarpophalangeal joint in a patient with early rheumatoid arthritis. Images courtesy of G Sakellariou.*

US is a routinely available, dynamic, non-invasive and relatively inexpensive bedside imaging method that allows for a multiplanar assessment of the musculoskeletal system, with high patient acceptability. In addition, a multi-joint assessment can be performed during the same scanning session.

Recent advances in technology have led to an extraordinary improvement in the quality and level of US equipment, with production of machines that offer good visualisation of most superficial and deep musculoskeletal structures. In particular, the great resolution of anatomic details at the level of superficial musculoskeletal structures imaged by high frequency transducers has promoted an increasing use of MSUS both in rheumatologic routine clinical practice and in research settings. In addition, the enhanced sensitivity for detecting low velocity flow in small synovium, tendon and enthesis vessels achieved by recent colour Doppler and PD techniques has led to the incorporation of Doppler US in rheumatology. The difficulties in detecting abnormalities within deep joints by physical examination facilitate the applications and use of US also in the assessment of pathology at the level of large joints.

MSUS allows an immediate correlation between imaging findings and clinical data, which improves diagnosis and management of patients with a range of rheumatic diseases from inflammatory arthritis, vasculitis or OA to soft tissue diseases.

4.1 Rheumatoid arthritis

In patients with RA, US demonstrates a wide range of elementary lesions. It provides detailed information on the quantity and characteristics of the fluid collection, the presence of synovial hypertrophy, and the integrity of articular cartilage and bony surface. US is also useful in supporting differential diagnosis, in monitoring the disease course, and in stratifying disease severity once the diagnosis is made.

4.1.1 Elementary lesions

US allows direct visualisation of most features of inflammatory arthritis, including effusion, synovial hypertrophy, tenosynovitis and bony erosions (figures 24–27).

Effusion is defined as ‘abnormal hypoechoic or anechoic intra-articular material that that can be displaced and compressed, but does not exhibit a Doppler signal’, while synovial hypertrophy/proliferation (figure 24) is defined as ‘abnormal hypoechoic intra-articular tissue that is non-displaceable and poorly compressible and which may exhibit a Doppler signal’ (Wakefield et al, 2005).

Tenosynovitis (figure 25) is defined as ‘hypoechoic or anechoic thickened tissue with or without fluid within the tendon sheath with possible signs of Doppler signals, which is seen in two perpendicular planes’ (Wakefield et al, 2005).

Figure 25 Ultrasonography (grey scale and power Doppler) demonstrating tenosynovitis of the extensor digitorum tendon in a patient with early rheumatoid arthritis, in transverse and longitudinal planes. Images courtesy of G Sakellariou.

Figure 26 Ultrasonography (grey scale and power Doppler) demonstrating synovial hypertrophy (SH) and erosive change (Er) in the fourth metacarpophalangeal joint in a patient with established rheumatoid arthritis. (Reproduced with permission from Brown et al, Clin Exp Rheumatol 2004;22:S18–25.)

The most typical RA lesion detectable by MSUS is RA bone erosion (figure 26), which is defined as an intra-articular discontinuity of the bone surface that is visible in two perpendicular planes.

Figure 27 Ultrasonography (grey scale and power Doppler) scoring system for metacarpophalangeal joints.

4.1.2 Diagnosis

The potential utility of US in the diagnostic work-up of early onset inflammatory polyarthritis relies on the detection of bony erosions and on the accurate assessment of joint inflammation. However, a recent study demonstrated the high prevalence of isolated effusion, as compared to synovial hypertrophy, in small joints of healthy subjects, suggesting that effusion should not be considered as a sign of joint inflammation in the absence of synovial hypertrophy (Padovano et al, 2016*)

Several studies have evaluated the performance of US in detecting bony erosions in comparison with conventional radiography, MRI and CT scan.

MSUS has consistently been demonstrated to be more sensitive than conventional radiography at detecting bone erosions in the hands, wrists, feet and shoulder in RA (Alasaarela et al, 1998; Backhaus et al, 1999; Wakefield et al, 2000; Schmidt, 2001; Backhaus et al, 2002; Hermann et al, 2003; Weidekamm et al, 2003;

Lopez-Ben et al, 2004; Magnani et al, 2004; Scheel et al, 2006; Szkudlarek et al, 2006; Grassi and Filippucci, 2007*). This is largely explained by the multiplanar nature of an MSUS assessment and its ability to detect small lesions. Wakefield et al (2000) detected 6.5 times more erosions in the MCP joints of patients with early RA using MSUS than were visible on X-ray compared to 3.4 times in established disease. MRI was used to successfully corroborate the accuracy of the MSUS results and the same study also reported a high level of intra- and inter-observer reliability of the MSUS findings. MSUS is particularly valuable for detecting erosions at the second and fifth MCP and fifth MTP joints, but sensitivity is reduced where probe access is more difficult, particularly the third and fourth MCP and intercarpal joints.

However, the clinical relevance of US joint erosions in terms of diagnostic properties is highly variable and depends on the site and dimension of erosive changes. Erosions in the fifth MTP are the best candidate to increase the probability of RA diagnosis in patients with arthritis.

The longitudinal progression of erosions on MSUS has not been extensively evaluated, but in a single study, erosive progression was seen more often on MSUS and MRI over a 2-year period than on radiographs, implying that these imaging techniques may be more sensitive measures of change in bone damage than conventional radiography (Backhaus et al, 2002). Another study has demonstrated the ability of MSUS to follow erosion progression over a 6-month period, although in this particular paper, MSUS identified a lower number of erosions than either MRI or radiography (Klarlund et al, 2000).

Rather than a direct application of US as a diagnostic test of RA, the combination of clinical and US findings may help in improving diagnosis in the earliest phases of the disease, in which classification may not be made by standard clinical, laboratory and radiographic data. Two different algorithms combining clinical and US findings have shown a satisfactory accuracy in the identification of early-onset undifferentiated arthritis evolving towards RA over time (Freeston et al, 2010; Salaffi et al, 2010).

As for MRI, the ACR/EULAR 2010 criteria for RA (Aletaha et al, 2010) have added a role of US in the diagnosis of RA, allowing MRI and US to be used to determine the joint involvement (Aletaha et al, 2010; Ostergaard et al, 2010*; Aletaha et al, 2011).

4.1.3 Monitoring and scoring

Accurate assessment of disease activity and joint damage in RA is important for monitoring treatment response. Several MSUS scores have been used for assessing and monitoring RA disease activity, and only recently a consensus on a reliable and sensitive to change instrument has been reached (Ohrndorf et al, 2013). Different semiquantitative (0–3) systems and quantitative measurements are used at joint level to quantify elementary lesions: joint effusion, synovial hypertrophy, tenosynovitis, PD synovitis and bony erosions (table 1)

Table 1 Different scoring systems proposed at joint level

		Elementary lesions	Grading	Joints
Szkudlarek	2003	Effusion, synovial hypertrophy, PD synovitis, erosion	0–3	Unilateral MCP II, III, PIP II, MTP I, II
Scheel	2005	Synovitis	0–3	Unilateral MCP II–V, PIP II–V
Naredo	2005	Effusion, synovial hypertrophy, PD	0–3	Sum of bilateral 60-, 18-, 16-, 12-, 10-, 6-joint score
Backhaus	2009	Synovitis, tenosynovitis/paratenonitis, PD synovitis, bone erosions	0–3 0/1	Unilateral wrist, MCP II, III, PIP II, III, MTP II, V
Ellegaard	2009	PD synovitis	0–3	Unilateral wrist
Dougados	2010	Synovitis	0–3	Bilateral 28 joints vs 38 joints (28+MTPs) vs 20 joints (20 MCPs+20 MTPs)
Hammer	2011	Synovitis; tenosynovitis, PD, bursitis	0–3	Bilateral 78 joints vs 44 joints 28 joints 12 joints 7 joints
Perricone	2012	Effusion, synovial hypertrophy, PD synovitis	0–3	Wrists, II MCPs, knees
Naredo	2013	Tenosynovitis, PD	0–3	Wrist extensor compartments, two finger flexor tendons and two ankle tendons
D'Agostino	2016	Synovitis, GS and PD combined score (GLOESS)	0–3	Bilateral 22 joints

MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint; PD, power Doppler; PIP, proximal interphalangeal joint.

Szkudlarek et al (2003a) developed a four-step semiquantitative US grading system separately for joint effusion, synovial thickening, bone erosion, and PD activity of five preselected small joints (unilateral MCP II, III, PIP II and MTP I, II joints examined from a dorsal aspect). Joint effusion was defined as a compressible anechoic intracapsular area and the amount of fluid semi-quantitatively scored as follows: grade 0: no effusion; grade 1: minimal amount; grade 2: moderate (without distension of the joint capsule); grade 3: extensive (with distension of the joint capsule). Synovial thickening was defined as a non-compressible hypoechoic intracapsular area scored as follows: grade 0: none; grade 1: minimal synovial thickening; grade 2: synovial thickening bulging over the line linking tops of the periarticular bones without extension along the bone diaphysis; grade 3: synovial thickening bulging over the line linking tops of the periarticular bones with extension to at least one of the bone diaphyses. Bone erosions were defined as follows: grade 0: normal bone surface; grade 1: bone surface irregularity without the defect being seen in two planes; grade 2: defect of the surface in two planes; grade 3: bone defect creating extensive bone destruction. Semiquantitative grading of the PD evaluation was as follows: grade 0: no flow; grade 1: single vessel signals; grade 2: less than half of the area of the synovium filled with vessels; grade 3: more than half of the area of the synovium filled with vessels.

The overall disease activity or damage can be quantified by accumulating findings from different sites into scores at the patient level, which can be monitored over time.

In the development of US multi-joint cumulative scores, several studies have analysed different numbers of joint scores, and all studies reached the conclusion that reduced summated scores provide a good reflection of overall inflammatory activity in RA (Szkudlarek et al, 2003a; Scheel et al, 2005; Naredo et al, 2005b; Backhaus et al, 2009; Ellegaard et al, 2009; Dougados et al 2010; Hammer et al, 2011; Perricone et al, 2012; Naredo et al, 2013).

All the scoring systems presented assessed the most frequently affected joints in RA and included the components of synovitis such as synovial hypertrophy, effusion and PD activity (table 1). Moreover, in some of them periarticular involvement is also assessed. In addition, a new scoring system—Global OMERACT-EULAR Sonography Scoring (GLOESS)—has been recently developed and represents a promising novel tool to measure synovitis in RA (Iagnocco et al, 2014, D’Agostino et al, 2016b*).

4.1.4 Prognostication

US is a tool that can help clinicians to predict disease progression and the development of joint damage in early RA patients. Initial evidence came from Taylor et al (2004), who investigated US-detected synovial thickness (using grey scale US (GSUS)) and vascularity (using power Doppler US (PDUS)) as predictors of radiographic joint damage of the hands and feet after 1 year. They found that a high baseline PDUS signal at the MCP joints correlated with radiographic joint damage over the following year in patients receiving methotrexate. Naredo et al (2007) confirmed this result by studying 42 early RA patients, who were followed up using PD after the initiation of disease modifying antirheumatic drug (DMARD) therapy. US imaging was carried out at 3, 6 and 12 months and radiographic progression monitored over a 12-month period. GSUS and PDUS were performed at 28 joints including shoulders, elbows, wrists, hands and knees. Time-integrated PDUS values were strongly correlated with DAS28 (Disease Activity Score 28) after 1 year and with radiographic damage progression measured by the SvdH (Sharp/van der Heijde) score. The implication from these studies is that highly vascular and inflamed rheumatoid synovium may contribute to the development of bone erosion and is therefore an important imaging biomarker in early RA.

A recent study examined this question prospectively over 2 years in patients with established RA and found that evidence of baseline US synovitis (PDUS scores) did increase the risk of structural damage progression (on X-ray) with an OR of 1.75, but clinically detected synovitis also predicted damage with an OR of 2.01, implying equivalence (Dougados et al, 2010). The authors concluded that the assessment of synovitis was important for predicting subsequent structural deterioration, irrespective of whether the joints were examined clinically or using US.

However, in a setting in which clinical assessment is not sensitive enough to identify inflammation and define clinical remission, a considerable body of evidence now exists in support of the use of US in the assessment of residual disease activity. It is well recognised that some patients with RA in clinical remission still have radiographic progression. Brown et al (2008) have investigated the predictive value of subclinical inflammation in terms of radiographic progression. This study clearly indicated that the patients with PD signal in clinical remission had the highest risk of progressive joint damage. This result has been confirmed in other studies. Analysing RA patients in clinical remission, it has also been shown that the presence of subclinical inflammation detected by US may help in discriminating patients with short-lived or unstable clinical remission. In particular, several reports support that patients with PD positive synovitis showed a significantly increased risk of early relapse compared with PD negative synovitis (Scirè et al, 2009; Foltz et al, 2012; Saleem et al, 2012).

A recent publication summarizes the evidence of the clinical utility of US for the management of RA in clinical practice by addressing the evidence of the literature and the experts' experience (D'Agostino et al, 2016a*).

4.1.5 Summary/clinical utility

US can be used to visualise all structures involved in RA except subchondral bone, at multiple joint sites at the same time. Diagnostic utility is specially enhanced by the combination of clinical and imaging findings, and also in the application of classification criteria for RA. US is a promising tool to monitor disease activity over time and to readily assess persistence of subclinical inflammation, and to drive decision-making in clinical practice.

4.2 Spondyloarthritis

Studies on the application of US in SpA are less systematic than in RA. However, most of the results achieved in research on RA can be extended to SpA. US allows the visualisation of most of the relevant joint pathologies associated with SpA, including enthesitis, bone erosions, synovitis, dactylitis, bursitis and tenosynovitis.

4.2.1 Elementary lesions

Though synovial inflammation and bony erosions do not show distinctive features compared to RA, in SpA US can also demonstrate some peculiar characteristics such as enthesitis, dactylitis and sacroiliitis.

A clear consensus US definition of enthesitis has been recently proposed by the OMERACT US working group (Terslev et al, 2013), even if the following broader definition of enthesopathy, proposed by the same group is still applied: “abnormally hypoechoic (loss of normal fibrillar architecture) and/or thickened tendon or ligament at its bony attachment (may occasionally contain hyperechoic foci consistent with calcification) seen in two perpendicular planes which may exhibit Doppler signal and/ or bony changes including enthesophytes, erosions or irregularity” (Figure 28) (Wakefield et al, 2005).

Figure 28. Ultrasonography (grey scale and power Doppler) pattern of a SpA related enthesitis demonstrating thickening of the enthesis insertion, erosions of cortical bone, Doppler signal at enthesis insertion but also in the body of tendon and in the bursa, in a patient with an enthesitis of the Achilles tendon insertion.

Dactylitis may be readily demonstrated by US as subcutaneous soft tissue enlargement, flexor tenosynovitis and adjacent synovitis. However, a valuable heterogeneity in frequency of soft tissue involvement and synovitis has been found, while flexor tenosynovitis findings are consistently reported (Bakewell et al, 2013).

Sacroiliitis may be demonstrated using colour and duplex Doppler US, or microbubble contrast-enhanced colour Doppler US. In AS, US has in one study been reported to show good sensitivity and specificity for the diagnosis of active sacroiliitis, using MRI as reference standard (Klauser et al, 2005). However, US can only visualise the most posterior part of the joint limiting its ability to assess the joint, including its sensitivity in detecting anatomical changes compared to other techniques such as MRI and CT.

4.2.2 Diagnosis

US has a greater sensitivity than clinical examination and other imaging techniques for the detection of peripheral involvement of SpA (Balint et al, 2002b).

Several studies have tried to use imaging techniques, including US, to demonstrate different patterns of joint involvement between SpA and other rheumatic diseases (Gutierrez et al, 2011). However, US synovitis, erosion and tenosynovitis in SpA do not substantially differ from those observed in other inflammatory arthritides (D'Agostino et al, 2010*).

US is able to clearly depict enthesal pathology and would appear to be the best candidate tool for the discrimination between spondyloarthropathies and RA.

Several studies have highlighted the diagnostic value of US in assessing the inflammation of enthesitis in SpA (D'Agostino et al 2016c*). A significant proportion of SpA patients (including PsA) have been found to have subclinical enthesitis using US. Balint et al (2002b) showed that 22% of entheses assessed were abnormal on clinical examination and 56% were abnormal on GSUS. D'Agostino et al (2003) used PDUS to assess multiple enthesal sites (greater trochanter, pubis, patella, Achilles tendon, plantar fascia, medial and lateral epicondyles) and showed that GS enthesal involvement on US of at least one of these sites is seen in 98% of patients with SpA including PsA, but is far less common in controls with mechanical back pain (44%) or RA (60%) (D'Agostino et al, 2003). The authors also demonstrated that the clear difference in the US enthesal involvement between SpA and the other diseases was made by the presence of enthesal vascularization in SpA patients which was never detected in RA and in mechanical back pain patients. Falsetti et al (2003) looked specifically at the calcaneal enthesitis using GS US and plain radiography comparing patients with PsA, RA and OA. There was no significant difference found between the PsA and RA groups, but there was a trend towards more Achilles enthesitis and plantar fasciitis in PsA and more erosive disease in patients with RA. Freeston et al (2012) assessed 42 patients with new-onset PsA (median disease duration 11.1 months) and 10 control subjects with clinical examination and GS/PD US of a standard set of entheses and found the prevalence of subclinical enthesitis in this early PsA cohort was low. It should be noted that the US equipment is of outmost importance when studying enthesitis, as the Doppler modality, which makes the difference in defining an SpA/PsA related enthesitis can be different according to the quality of the machine (Torp-Pedersen et al, 2015*).

4.2.3 Monitoring and scoring

The use of US as an objective outcome measure has also been expanding in SpA. The majority of US studies on synovitis have used definitions and scoring systems developed in the setting of RA.

One of the main issues in SpA, compared to RA, is related to the set of joints to be assessed. Given the wide diversity of joint involvement between specific diagnoses and individuals, a restricted joint evaluation is less valid to evaluate the overall disease activity or damage in these patients (Ficjan et al, 2014)

Several US enthesitis assessment tools have been developed in SpA cohorts. The Glasgow Ultrasound Enthesitis Scoring System (GUESS) tool examines five lower limb sites (Achilles, quadriceps, superior and inferior patellar tendons and plantar fascia) (Balint et al, 2002b), while the Madrid Sonographic Enthesis Index (MASEI) assesses six sites (five as before plus the triceps tendon) (De Miguel et al, 2009). Using these tools, US has been shown to be more sensitive than clinical examination for detecting enthesitis in established SpA cohorts (De Miguel et al, 2009; Naredo et al, 2011). However, it should be noted that these scoring systems have been developed for diagnostic purposes and are not suitable for evaluating therapeutic response as

mainly based on GS structural abnormalities. The OMERACT US group is working on a scoring system suitable for evaluating responsiveness.

4.2.4 Prognostication

In contrast to RA, no longitudinal studies of the prognostic severity value of US findings in SpA are available. One study evaluated the prognostic value in term of early diagnosis in a cohort of patient with suspected SpA (D'Agostino et al, 2011*)

4.2.5 Summary/clinical utility

US can be used to visualise articular and peri-articular structures involved in SpA, particularly enthesitis. A valid and reliable definition of elementary lesions and a system for monitoring of disease activity and damage is required to develop prospective studies which can elucidate the impact of US abnormalities on differential diagnosis, prognostic stratification and evaluation of treatments in SpA.

4.3 Osteoarthritis

Plain radiography is considered the gold standard for assessing OA bony abnormalities and indirectly evaluates articular cartilage damage. However, this technique is limited by its inability to directly visualise articular cartilage, synovial recesses, the peripheral aspect of the menisci and other soft tissues involved in the pathophysiology of OA. High resolution MSUS offers an overall assessment and follow-up of the joints in OA. It provides valuable information that fills the gap between clinical and radiological evaluation. MSUS of the peripheral joints can be easily carried out at the time of consultation, allowing an immediate correlation between clinical and imaging findings, which may improve the diagnosis and management of patients with OA.

The articular cartilage, bone contour, synovial recesses, tendons, ligaments, bursae and peripheral aspect of the menisci can be evaluated by US.

In addition, MSUS can be routinely used to guide accurate and safe diagnostic or therapeutic injections in the OA joints. Some technical limitations of MSUS can reduce its diagnostic capability in OA, including limited acoustic windows for cartilage and bony cortex assessment in some joints (eg, hip, glenohumeral), lack of visualisation of bone marrow abnormalities, low sensitivity of current Doppler modalities in deep/large joints (eg, hip, glenohumeral), and operator dependence.

4.3.1 Which pathologies are visualised by US?

In OA, US is appropriate for the assessment of joint inflammatory changes such as effusion and synovial hypertrophy. In addition, due to their sensitivity in demonstrating pathological vascularisation within the synovial tissue, Doppler modalities can show synovitis and differentiate between active and inactive

inflammation (Maksymowych and Landewe, 2006*; Ostergaard et al, 2008*). OMERACT definitions for effusion and synovial hypertrophy developed in RA can also be applied in OA.

US is also able to demonstrate the signs of structural damage involving the hyaline cartilage and the bony cortex at joint margins.

The correct use of appropriate acoustic windows at different joint sites is fundamental for imaging articular cartilage by US: maximal flexion for hand and knee, extension for elbow, wrist, ankle and foot, and in intra-rotation/extra-rotation for hip and shoulder. With a correct, perpendicular insonation of the structure by the US beam, in healthy joints the cartilage typically has a well-defined anechoic echotexture with sharp, regular and continuous margins.

The anterior interface, localised between cartilage and soft tissues, is thinner than the posterior edge, visualised between cartilage and bony cortex. According to the size of the joint, the thickness of the cartilage varies between 0.1 and 0.5 mm (hand and foot) and 3 mm (knee) and is accurately measured with current high tech equipment that allows even sub-millimetre measurements. Assessment of the contralateral site to perform complete comparisons is always recommended.

US is able to demonstrate a wide set of cartilage abnormalities in OA. In early disease, loss of sharpness and irregularities of surfaces are imaged and initially involve the superficial edge. These abnormalities, which correspond to tissue degeneration and cleft formation, are followed by echotexture changes with inhomogeneous hypoechogenicity, and, later on, by focal and asymmetric thinning up to the complete absence of the cartilaginous layer that is related to cartilage breakdown and bony denudation.

Bony cortex is imaged by US as a hyperechoic, regular and continuous surface. It has a linear shape that becomes curvilinear at the joint margins. Osteophytes are characteristic findings in OA and are imaged by US as a step-up of the bony prominence at the end of the normal bone contour, or at the margins of the joint seen in two perpendicular planes, with or without acoustic shadow.

The high sensitivity of US in showing bony cortex changes has been widely reported and, in erosive hand OA, erosions are imaged as intra-articular discontinuities of the bone surface visible in two perpendicular planes. Even in this case, OMERACT definitions for erosions in RA can also be applied in OA. They can be detected with varying degrees of clarity related to the interposition of osteophytes, which may determine narrowing of the acoustic window (Plant et al, 1998).

The involvement of joint structures such as ligaments and menisci or periarticular bursae can be evaluated by MSUS.

Meniscal degeneration, degenerative meniscal tears and parameniscal cysts are common findings in knee OA. Protrusion of the medial meniscus of the knee with displacement or distension of the medial collateral ligament and the medial joint capsule are frequently detected by MSUS in patients with medial femorotibial OA.

Baker's cyst is commonly found in knee OA. It results from pathological fluid distension of the gastrocnemius-semimembranous bursa that communicates with the knee joint in adults. Baker's cyst can be symptomatic by itself, independently of the degree of accompanying knee synovitis, and has been associated with knee pain in OA (Machold et al, 2002; Spoorenberg et al, 2004). Baker's cysts are easily identified and their aspiration and injection can be safely guided with MSUS.

4.3.2 *Diagnosis*

As recently reported in a systematic literature review, US studies compared patients with hand OA with healthy controls and reported significant differences in joint space narrowing (JSN), osteophytes, synovitis, PD signal and joint effusion, while no significant differences were found for tendon effusion (Saltzherr et al, 2014). In studies comparing structural US changes with conventional radiography, US generally detected more osteophytes, erosions and JSN. Only one study detected fewer erosions with US (sensitivity = 0.73, specificity = 1.0). Joint pain, tender joints and swollen joints agreed poorly with grey scale US measurements of synovitis, effusion, PD measurements, JSN, and osteophytes.

The diagnostic performance of knee US for the detection of degenerative changes of articular cartilage has been tested using arthroscopy as the reference standard. Positive US findings were specifically associated with cartilage degeneration, but with limited sensitivity.

4.3.3 *Monitoring and prognostication*

A few studies found significant association between US-detected inflammatory features and knee pain and function.

Chao et al (2010) evaluated US as a predictor of clinical response to intra-articular glucocorticoid injections in patients with knee OA, and found a significantly higher improvement in pain among non-inflammatory patients than among inflammatory patients 12 weeks after injection.

A cross-sectional European study performed under EULAR umbrella analysed 600 patients with painful knee OA and found that US-detected synovitis and or effusion were present in 53% of the examined patients (D'Agostino et al, 2005) and correlated with advanced radiographic OA and clinical signs and symptoms suggesting an inflammatory flare. In addition the follow-up of the same cohort demonstrated that the presence of an US detected effusion at baseline was predictive of a joint prosthesis replacement at 2 and 5

years of follow-up. (Conaghan et al, 2010). However, US-detected synovitis was not a predictor of subsequent joint replacement.

One US study reported a significant decrease in PD and effusion in patients treated with intra-articular hyaluronic acid injections. These decreases correlated with a significant reduction of pain ($r = 0.7$ and $r = 0.8$) (Klauser et al, 2012). The other US study reported a small non-significant decrease in synovitis in patients treated with intramuscular methylprednisolone injections, while there was a significant decrease in pain.

A preliminary US scoring system for features of hand OA includes semiquantitative evaluation of synovitis in 15 joints of the hand, with a moderately good intra-reader and inter-reader reliability (Keen et al, 2008).

Metric properties of this and other scores are still to be systematically evaluated.

4.3.4 Summary/clinical utility

US allows accurate assessment of the periarticular and intra-articular structures involved in the osteoarthritic joint in clinical practice. Technological development will probably enhance the role of US in the assessment of cartilage, bony cortex and inflammation in both clinical practice and research.

5 Nuclear imaging

Nuclear medicine imaging is based on the detection of gamma rays emitted from unstable isotopes as they decay. For each isotope of ^{99m}Tc , a single gamma ray is directly emitted during decay, while for ^{18}F , which emits positrons, two gamma rays are emitted indirectly.

Before the scan, the patient is injected with the radioisotope and a certain time interval elapses.

During the scanning procedure, gamma rays are emitted from the patient and registered by an external detector (gamma camera) producing the scintigraphic image. When the gamma camera is orbited around the patient, three dimensional tomographic images can be made of the gamma rays emitted and hence the technique is called single photon emission CT, or SPECT. A combination of biologically active molecules and an unstable isotope are called radiopharmaceuticals. These include fluorine-18 labelled fluoro-2-deoxy-D-glucose (^{18}F FDG), autologous white blood cells, labelled with ^{99m}Tc or ^{111}In , ^{99m}Tc -labelled bisphosphonates, such as methylene diphosphonate or hydroxymethylene diphosphonate, ^{67}Ga -citrate, ^{99m}Tc -labelled nanocolloids, and ^{99m}Tc - or ^{111}In -labelled proteins, such as IgG or albumin. None is specific for inflammation, and none offers the possibility of directly distinguishing the aetiology of the underlying inflammatory process.

The accumulation of these agents in inflamed tissues is based on different mechanisms: uptake into inflamed tissue as a result of increased metabolism, either of inflammatory cells or of tissue-specific cells with increased

activity as a reaction to inflammation; unspecific accumulation in the site of inflammation as a result of increased blood flow and enhanced vascular permeability.

5.1 Scintigraphy

The first nuclear medicine imaging technique applied to detect joint inflammation in RA was 99mTc-immunoglobulin G (99mTc-IgG) scintigraphy (de Bois et al, 1995).

Localisation of 99mTc-diphosphonate to periarticular bone is related to both osteoblastic activity and skeletal vascularity (figures 28 and 29). Thus, it is interesting that joint uptake of this tracer in early RA has been shown by several groups to predict later bone erosion. A 2-year multimodality observational study by Palosaari et al (2006) showed that 99mTc-nanocolloid (99mTc-NC) scintigraphic uptake predicted MRI erosion score progression from baseline to 2 years ($r = 0.45$) but was closely correlated with other baseline predictors. On multivariate analysis, only MRI bone oedema maintained significance (OR 4.2, 95% CI 1.3 to 13.8) (Olivieri et al, 2002). MRI bone oedema has been shown to be a vascular lesion by Hodgson et al (2008). Hence, this could be at least part of the explanation why scintigraphic joint activity so closely parallels MRI bone oedema/osteitis.

Figure 29 Nuclear medicine isotope bone scan demonstrating symmetrical uptake in the metacarpophalangeal and wrist joints in a patient with rheumatoid arthritis. Images courtesy of AK Brown.

Scintigraphy has recently been extended as an imaging modality by the development of radiopharmaceuticals, formed by conjugating the isotope with molecules that have biological activity relevant to the inflammatory process. In one proof-of-concept study, [99mTc]–infliximab scintigraphy of inflamed joints predicted the response to anti-TNF treatment in a group of RA and AS patients. Responders demonstrated a much greater increase in pre-therapy tracer uptake within affected joints than non-responders ($p = 0.00001$) (Williamson et al, 2004). Another group used anti-human TNF α labelled with 99mTc to evaluate joint inflammation in eight RA

patients. The sensitivity and specificity for the nuclear imaging technique versus MRI were 89.8% and 97.3%, respectively (Roimicher et al, 2011).

Figure 30 Nuclear medicine isotope bone scan demonstrating widespread increased isotope uptake in wrists, spine, ribs, hips, knees, and ankles. This patient has metastatic bone disease. Images courtesy of AK Brown.

5.2 Single photon emission CT

SPECT bone scintigraphy has improved the accuracy of isotope bone scanning. This technique is now available in most nuclear medicine departments and provides additional information enabling more precise interpretation as well as functional data to complement other cross-sectional imaging techniques, such as MRI and CT. The basic methodology of standard scintigraphy applies, but in addition it involves rotating the gamma camera around the patient and using computer software to reconstruct tomographic images in any plane. Additionally, camera sensitivity is improved by using modern cameras with two heads. Image acquisition typically takes 30 min. The result is increased contrast resolution and greater sensitivity but also improved anatomical localisation and more precise definition of an area of interest, which also improves specificity (Haavardsholm et al, 2008).

SPECT has been applied in a number of clinical settings (figure 30). The most common situation is evaluation of spinal pathology in vertebral bodies, posterior vertebral elements, facet joints, pars inter-articularis defects, neoplastic disease and evaluation of post-surgical cases, with most studies reporting increased sensitivity

compared with standard three-phase scintigraphy and conventional radiography. Other indications include suspected avascular necrosis of hips, the diagnosis of meniscal tears in the knees, temporomandibular joint dysfunction and evaluation of lesions at the base of the skull. Again there is evidence to support increased diagnostic utility compared with standard three-phase scintigraphy and conventional radiography (Haavardsholm et al, 2008).

Figure 31 Single photon emission CT image of the hand from a patient with early rheumatoid arthritis showing increased uptake of tracer at several joints, most marked at the fourth metacarpophalangeal joint (proximal and distal regions, circle). (Reproduced with permission from McQueen, *Best Pract Res Clin Rheumatol* 2013;27:499–522.)

SPECT has also been used to assess functional brain abnormalities in neurological disease. This technique has been applied to the investigation of patients with systemic lupus erythematosus (SLE) exhibiting neuropsychiatric manifestations, with some studies demonstrating regional hypoperfusion (Appenzeller et al, 2007), although other studies have shown similar results in SLE patients without neurological disease (Hetland et al, 2010). SPECT has also been used to detect abnormal regional cerebral blood flow in patients with fibromyalgia (Benton et al, 2004).

Recent advances include correlation of the anatomical and functional information presented by SPECT and CT which can aid in the clinical decision-making process by enabling better localisation and definition of organs and lesions.

Ostendorf et al (2010) investigated multi-pinhole SPECT (MPH-SPECT) in early RA (<6 months' disease duration) and OA patients and compared results with bone scintigraphy and MRI. MPH-SPECT detected more positive joints than bone scintigraphy (80 vs 26 joints in 21 and 13 patients, respectively). The mean tracer uptake in affected joints was threefold higher than in unaffected joints but this did not differ between OA and RA patients. However, investigators noted that the pattern of tracer uptake on MPH-SPECT images allowed differentiation between RA and OA joints in the majority of patients whereas this was not possible on review of bone scintigraphy images. In 11/13 RA joints, pathological tracer accumulation on MPH-SPECT images matched MRI bone marrow oedema and erosions. In two patients there was increased MPH-SPECT uptake without evidence of bone oedema on MRI (synovitis alone). These findings suggest that radionuclide SPECT imaging could be more sensitive to very early disease than 1.5 T MRI scanning and suggest a potential role in RA diagnosis.

5.3 Positron emission tomography

Positron emission tomography (PET) is a nuclear imaging technique based on positron-emitting radioisotopes. A positron loses energy during collisions with atoms and finally becomes annihilated after collision with an electron, resulting in the formation of two perpendicular gamma rays. PET detectors register these two photons along with their orientation. Circular PET detectors simultaneously register photons from multiple projections. Concomitant CT scanning enhances anatomic definition and spatial localisation.

Usually, PET studies have been performed with [18F] fluorodeoxyglucose ([18F]FDG), which is a radiolabelled glucose analogue that accumulates in metabolically active tissue, as actively inflamed tissues. Increased uptake of [18F]FDG is mediated through glucose transporters type 1 (GLUT1) and type 3 (GLUT3) on the cell surface. [18F]FDG is rapidly phosphorylated to [18F] FDG-6-phosphate by hexokinase, but cannot undergo further metabolism, effectively trapping this molecule intracellularly.

This technique has been used to assess disease activity (Beckers et al, 2004; Goerres et al, 2006) and metabolic changes in response to treatment (Palmer et al, 1995; Beckers et al, 2006). It may have a role in the assessment of early inflammatory arthritis as, like a traditional isotope bone scan, it can provide a high degree of sensitivity in detecting early signs of inflammation in multiple joints, but in addition quantification of 18F FDG uptake may be used to assess disease activity which can be directly compared to follow-up imaging. Using extrapolations from oncology data, it has been speculated that the degree of intensity of 18F FDG uptake may correlate with more aggressive inflammation which may relate to prognosis (Brown et al, 2008). With regard to monitoring response to therapy, Palmer et al (1995) reported that quantitative 18F FDG PET helped to detect metabolic changes as measures of response to therapy that were not apparent with conventional measures of disease activity. In addition, a recent pilot study by Beckers et al (2006) in RA patients treated with TNF α blocking therapy demonstrated close correlations between the PET findings and MRI and US

assessments of the synovitis, and biochemical markers of disease activity such as CRP and matrix metalloproteinase-3.

Gent et al (2012) used macrophage targeting with [11C] PK11195 PET to detect subclinical joint inflammation in a group of 29 anti-citrullinated protein autoantibody (ACPA)-positive patients with arthralgia (pre-RA). Small joints of the hands and wrists were assessed for tracer uptake and scored 0–3 for each joint. Patients were then observed for 24 months, looking for the development of clinical arthritis. PET-positive joints were found in four patients at baseline, and within 2 years of follow-up all had developed RA. There were another five patients who were scan-negative at baseline but who also developed clinical RA. Three of these developed joint involvement outside the PET field of view used in this study. Inter-observer reader reliability data were presented with kappa values of 0.91 (95% CI 0.74 to 1) at the patient level and 0.81 (95% CI 0.65 to 0.96) at the joint level.

Other promising indications for 18F FDG PET include assessment of disease activity and the extent of inflammation in large vessel vasculitides such as giant cell arteritis and Takayasu's arteritis (Walter et al, 2005; Dasgupta et al, 2007) (figure 31). Furthermore, this technique may demonstrate inflamed soft tissues in the shoulder and hip region as well as along the processi spinosi in active polymyalgia rheumatica (Blockmans et al, 2007).

Figure 32 Positron emission tomography scan in a patient with large-vessel vasculitis (aortitis) demonstrates characteristic fluorine-18 labelled fluoro-2-deoxy-D-glucose (18F FDG) uptake in the wall of the aorta visualised in coronal and axial sections. Image courtesy of WA Schmidt.

However, PET scanning is expensive and it is unlikely to become a routine imaging tool for the detection of musculoskeletal inflammation.

6 Conclusion

There are increasing data to support the validity of imaging tools such as conventional radiography, US, MRI, CT and nuclear medicine modalities in the evaluation of rheumatic diseases. Evidence supports their potential utility in facilitating prompt recognition of pathology, precise measurement of disease activity, sensitive monitoring of response to therapy, and effective assessment of disease outcome as well as challenging our understanding and providing valuable insights into disease pathogenesis. Therefore, musculoskeletal imaging is becoming an indispensable tool in the diagnosis and management of patients with rheumatic disease and an integral part of clinical rheumatology practice. This situation is likely to continue to evolve as a result of ongoing advances in research and technological development and application of these techniques to other disease areas.

SUMMARY POINTS

- Different imaging techniques should be used in a complementary way to investigate joint diseases; each technique has their own advantages and limitations.
- X-ray remains an important method of investigating structural damage; however, it is relatively insensitive in early disease.
- Ultrasound is a promising and feasible tool for the assessment of both soft tissue inflammation and structural damage in peripheral joints. It may be available in a clinical setting and can assess multiple joints in a relatively short period of time. Through the development of guidelines, reproducibility is now acceptable among trained examiners. Its main limitation is that a trained user needs to be present to examine the patient and that some areas are not accessible (an acoustic window is needed).
- MRI is the overall most sensitive tool for assessing inflammation in peripheral and axial soft tissue and bone, and (except for CT) for bone damage. In particular, MRI is the only modality which offers information on inflammation at the subcortical level, for example, bone marrow oedema. It is expensive and time consuming, however.
- CT is the gold standard for the assessment of structural damage but is limited by radiation exposure, especially for repeated examinations.
- Joint diseases are characterised by different pathological lesions which will influence the choice of imaging.
- Different scoring systems for different techniques and diseases have been proposed and validated; it is generally accepted to separate inflammatory parameters (eg, synovitis) from structural ones (eg, bone damage). EULAR/OMERACT scoring systems are widely recognised methods of assessment for inflammatory joint diseases using MRI and US.
- The potential role of imaging may be divided into (1) early diagnosis, (2) prognostication, (3) monitoring, and (4) treatment endpoint. Further work, however, is still required in some of these aspects, particularly with regard to their cost-effectiveness and added-value over standard clinical parameters.

IN-DEPTH DISCUSSION I

**The Utility of Ultrasonography in the management of
Psoriatic Arthritis**

Introduction

Psoriatic arthritis (PsA) is a chronic inflammatory joint disease which can present with a spectrum of clinical phenotypes, including axial disease, a rheumatoid arthritis-like form, peripheral oligoarthritis, predominant involvement of the DIPs or enthesitis. The enthesis is considered the primary site of pathology, however patients may also present with significant synovial abnormalities and bone erosions at the joints occur in up to 62% of subjects (Veale, 2000). PsA may result in significant disability, reduced quality of life and life expectancy (Muhammad et al., 2015). Early diagnosis has shown to lead to better outcomes (Kane et al., 2003) and this has become a central issue since effective treatments have been introduced (Ash et al., 2012).

Conventional radiography at peripheral joints may show bone apposition and bone erosions in patients with PsA, however, these may not be present in early disease and radiography is not particularly useful in detecting soft tissue involvement related to active disease. Over the past decade, ultrasonography (US) and MRI have been identified as useful techniques in inflammatory arthritis patients. Although MRI can produce simultaneous and multiplanar images of bone and soft tissues, its widespread use is limited by cost, availability and by the need to select a restricted number of joints to scan. MRI remains the reference technique for management of the axial disease, however in the assessment of peripheral joints US has also emerged as an imaging technique of value. This overview will therefore focus on the use of US for the peripheral joint and enthesal disease.

In the field of PsA, the potential role of US includes diagnosis, prognostication, monitoring and guiding intra and periarticular procedures. The use of US as a treatment endpoint has yet to be extensively investigated. US has several advantages: it is well tolerated by the patient, with the possibility of an interactive examination allowing rapid decision making, also it does not involve exposure to ionizing radiation. In PsA, US examination includes both a morphologic examination using grey scale and a functional examination in order to detect vascularised tissues using Doppler techniques.

Ultrasound and diagnosis

US has shown to be more sensitive than clinical examination in detecting joint inflammation (Backhaus et al., 2009) and more sensitive than conventional radiography in the detection of bone erosions in selected areas (Wakefield R et al, 2000) in patients with RA. Similar findings emerge in early PsA, in which subclinical synovitis, detected by GS and PD, was found in more than 75% of patients, in particular at the wrist (Freeston et al, 2014). Although there are no typical US patterns characterizing PsA synovitis, with the exception of a possible more intense intra-articular vascularization, US demonstrated a good accuracy in assessing synovitis in PsA (Coates et al 2012, Gutierrez et al. 2010; De Simone C et al 2011, Wiell C et al 2007; Sankvoski AJ et al 2013), as compared to other imaging modalities. In addition the presence of an US-detected synovitis has been shown

to be associated with long-term erosive radiological progression and poor outcome (Soriano et al, 2015). Also at the knee US more frequently detected synovial abnormalities compared to clinical examination (Delle Sedie et al., 2010). US has the ability to identify enthesitis, whose US definition has been recently renewed (Terslev et al., 2014). However, in this context a poor correlation between physical examination and US findings has been shown, with enthesitis being diagnosed more frequently by clinical examination than by US (Freeston et al., 2012). Thus US might emerge as a tool to reduce over-diagnosis of clinical enthesal involvement and potentially PsA over diagnosis.

When considering US for diagnostic purposes, it should be underlined that the technologic improvement in US equipment has led to the possibility of detecting mild abnormalities, especially with GS examination, in the joints of healthy subjects. PD at joint level can also be seen in healthy individuals, though less frequently (Witt et al., 2013, Padovano et al 2016).

Most diagnostic studies in PsA evaluated US to detect elementary lesions, however the role of comprehensive US evaluation in addition to clinical findings to increase the certainty of diagnosis has not been investigated. The use of US can be considered to confirm the presence of dactylitis, which is considered typical of the disease (Bakewell et al., 2013). Populations of patients with PsA and RA have been compared to identify features that might help differentiate these conditions. US at MCPs can demonstrate a pattern of peritendinous inflammation surrounding the extensor tendon, which was found frequently (65.8%) in patients with PsA but not in patients with RA (Gutierrez et al., 2011). At the finger joints enthesitis, tendon involvement and inflammation of periarticular tissues were seen exclusively in patients with PsA and never in RA patients (Lin et al., 2015).

US may also help distinguish between patients with fibromyalgia and those with multiple enthesal inflammation. Inflammatory changes, detected by PD, were more prevalent in patients with PsA, with the Achilles tendon and plantar fascia sites providing higher specificity for differentiating the two conditions (Marchesoni et al., 2012). An additional advantage of US is to show features of different or concurrent conditions, such as crystal-related arthritis or osteoarthritis.

Longitudinal scan of the 3rd finger in a patient with recent onset PsA, showing the region over the proximal interphalangeal joints. The superficial and deep flexor tendons (T) are surrounded by fluid (asterisks), the use of power Doppler (on the right) demonstrates hypervascularisation within the tendon sheath and in peritendinous tissues. These aspects are consistent with dactylitis. PP: proximal phalanx; DP: distal phalanx.

Longitudinal scan of the metacarpophalangeal (MCP): comparison of different power Doppler patterns in early PsA and early rheumatoid arthritis. A) Early PsA: power Doppler signal is located in the area surrounding the extensor tendon. B) Early RA: power Doppler is mainly located into the MCP and in contact with the bony surface. M: metacarpal bone; P: phalanx.

Longitudinal scan of the insertion of the Achilles tendon (T) at the calcaneus (C) in a patient with PsA. Arrowheads: presence of irregularity of the bony cortex at the tendon insertion. Arrow: enthesophyte.

Prognosis

US features as prognostic markers have been investigated more extensively in patients with psoriasis without arthritis. In this population, enthesal thickness was higher and the number of enthesophytes greater compared to healthy controls (Gisondi et al., 2008), although patients with PsA had still more severe enthesal involvement (17). No correlations were found between the extent of skin involvement and US alterations (Gutierrez et al, 2011). Also patients with isolated nail disease show higher enthesopathy and inflammation

scores than healthy controls (Ash et al., 2012). Preliminary evidence on 30 patients followed for up to 7 years supports the hypothesis that US enthesal abnormalities might predict the onset of arthritis, with the thickness of the quadriceps tendon independently predicting PsA onset (Tinazzi et al., 2011). A subsequent study evaluated the lower limb entheses of patients with psoriasis, PsA and healthy controls. Patients with psoriasis had higher scores for inflammation compared to healthy controls, while patients with PsA showed higher scores for both inflammatory and chronic components than patients with psoriasis and healthy controls. This supports the hypothesis of subclinical involvement in patients with skin psoriasis (Aydin et al., 2013).

In patients with a defined diagnosis of PsA, US abnormalities have been cross-sectionally correlated with measures of disease activity. A comprehensive US assessment, including joints and entheses, was significantly related to clinical disease activity ; in the same population, up to 66% of patients in clinical remission had still US joint and enthesal inflammatory involvement (Husic et al., 2014). The presence of synovitis and erosive changes has also been related to pain at the MTP joints (Turner et al., 2014).

Prognostic information from prospective studies is limited in PsA. The value of US to predict radiographic progression has been tested and higher scores of synovial hypertrophy and PD were shown to be predictive of radiographic progression, as well as higher GUESS scores (see below) (El Miedany et al, 2015).

Therefore, the prognostic application of US might play a role in patients with psoriasis, and might identify patients with a more severe disease course.

Disease monitoring

The use of US to monitor disease relies on the expertise of the operator and on the quality of the equipment, requiring also validated tools. In the context of PsA this assessment is made more complex by the presence of different structures of interest.

For enthesal assessment, two scores have been developed. The Glasgow Ultrasound Enthesis Scoring System (GUESS) (Balint et al., 2002) has been validated in a population of spondyloarthritides. This includes five enthesal sites at the lower limbs, evaluating bursitis, thickness, erosions and enthesophytes (each abnormality scored as present/absent). The GUESS correlates with radiographic progression (El Miedany et al., 2015), but it is not useful for sensitivity to change. The Madrid Sonographic Enthesis Index (MASEI) has been presented, including six enthesal sites at limbs. Calcifications, bursae, erosions, PD signal in bursa or enthesis, tendon thickness and structure are scored separately (de Miguel et al, 2009). The MASEI has demonstrated discriminative capacity between patients with spondyloarthropathy and healthy controls (de Miguel et al, 2011) and between patients with PsA, psoriasis and healthy controls (Eder et al., 2014).

Recently, in a prospective and longitudinal study an US composite score for the assessment of inflammatory (synovial and enthesal) and structural lesions in PsA was developed, which has shown to have good metric properties including a good sensitivity to change (Ficjan et al, 2014).

Ultrasound-guided procedures

Specific studies applying US to drive injections in PsA are not available, however, some information can be extrapolated from studies on arthritis populations. There are only two studies comparing US guided and blind injection techniques, supporting a greater accuracy of guided injections, possibly driving a better response (Sibbitt et al., 2012; Cunnington et al., 2010). Imaging could be of particular interest in injecting small and anatomically variable sites, to increase the accuracy and safety of the procedure, such as tendons (Di Gesso et al., 2012).

Conclusion

US has a potential role in several phases of the management of PsA. The technique can detect the main elementary lesions in the joints and in the entheses and this can be informative also in pre-clinical phases. In patients with psoriasis, US may help predict the development of PsA, and in patients with confirmed disease US findings may be helpful to characterise subsets with a more severe prognosis. Validated tools to monitor the disease are available and might be routinely applied in the future. US can also be useful in the clinical setting when intra-articular and peri-articular treatments are required.

IN-DEPTH DISCUSSION II

Imaging of Gout

Gout is characterised by the deposition of monosodium urate (MSU) crystals in joints, periarticular and soft tissue. The crystal deposition takes place when urate concentration raises above 6.8 mg/dl under physiological conditions, which is the uric acid saturation threshold (Loeb, 1972). This condition can lead to flares of acute arthritis and, in long standing disease, to a chronic arthropathy with intra-articular or extra-articular tophus formation, joint damage and associated complications.

Imaging techniques are useful in measuring inflammation, MSU deposits and damage, and they assist clinicians in the diagnosis and monitoring of gout and provide useful information on gout pathology.

Conventional radiography

Conventional radiography (CR) is the oldest most used imaging technique in gout. It is feasible, readily available and reliable, though it is not enough sensitive to evaluate soft tissues.

In early disease CR is usually normal or eventually may show non-specific soft tissue swelling around the acutely inflamed joint. Typical findings appear in long-standing disease and include: soft tissue opacifications (tophi), articular and peri-articular erosions with overhanging and sclerotic margins and new bone formation. (Watt, 1975)

Despite CR detected asymmetric swelling and sub-cortical cysts being included in the preliminary 1977 American Rheumatology Association criteria for gout (Wallace et al, 1977), their clinical usefulness in discriminating between different arthritis is limited. More specific signs of gout, such as soft-tissue opacifications with densities between soft tissue and bone, articular and peri-articular bone erosions and osteophytes at margins of opacifications or erosions showed sensitivity ranging from 5 to 26% and specificity from 95 to 100% (Rettenbacher et al., 2008). Given the low expected prevalence of specific CR signs in early disease, the relevance in diagnosis is limited.

However, CR can be successfully used in monitoring damage over time. A modified Sharp/van der Heijde scoring method has shown to be reliable and valid in gout (Dalbeth et al., 2007), supporting its use in practice and clinical trials.

In summary, CR may assist the diagnosis and monitoring damage of gout, but its low sensitivity limits its application in assessing inflammation, urate deposits and early signs of intra- and extra-articular damage.

Ultrasonography

Ultrasound (US) is an emerging imaging modality for gout. It is relatively inexpensive, readily available and ionising radiation-free. Reliability and validity are limited by the operator- and machine dependency, the availability of acoustic windows, and the inability to see beyond the bony surface.

An important diagnostic usefulness of US in gout is its use as a guide for synovial fluid aspiration (Gonçalves et al., 2011). Furthermore US seems to be able to detect deposits of MSU crystal over the cartilage, an US sign named ‘double contour’ sign, which is defined as “hyperechoic band over anechoic cartilage” (Grassi et al., 2006). (Figure 1)

The US appearance of tophi previously described as “hypoechoic to hyperechoic, inhomogeneous material often surrounded by a small anechoic rim” (Howard et al., 2011) has been recently reformulated and tested, along with other gouty lesions, in a series of Delphi and images and patients based reliability exercise performed within the OMERACT US group (Terslev et al, 2015a and b, Gutierrez et al. 2015)

Synovial membrane may show non-specific signs of hypertrophy and presence of power Doppler signal, but intra-synovial tophi or hyperechoic spots in synovial membrane are also detectable in patients with gout (Naredo et al., 2013). Hyperechoic spots in synovial fluid, called ‘snowstorm’ sign, can also be present in gout.

Finally, US can detect bony erosions (“breaks in hyperechoic cortical bone detectable in two perpendicular planes”) more sensitively than CR. (Wright et al., 2007).

Figure 1. Ultrasonographic features of gout. A. 2nd MCP with double contour sign (arrow) and power Doppler synovitis; B. 1st MTP with double contour sign (arrow) and intra-articular tophus (asterisk); C. MCP with extra-articular tophus (asterisk); D. Patellar tendon with extra-articular tophus (asterisk). (Image courtesy of Dr Georgios Filippou).

Several case control diagnostic studies have evaluated the accuracy of US for gout diagnosis compared with clinical diagnosis (crystal-proven or not). The sensitivity of the ‘double contour’ sign ranged from 21 to 92%, and specificity from 98 to 100%; while detection of tophi showed a sensitivity ranging from 0.23 to 100% and a specificity from 91 to 100% (Thiele et al., 2007, Ottaviani et al., 2012; Naredo et al., 2013; Gruber et al., 2014).

It is likely that the combination of clinical and US findings might optimise the diagnostic process of acute monoarthritis. (Lamers-Karnebeek et al., 2014)

Small studies have reported that US features of gout such as the double contour sign, hyperechoic spots in synovial fluid, hyperechoic cloudy areas, tophus diameter and volume improve in patients who reach the target of serum uric acid $\leq 6\text{mg/dL}$. (Villaverde et al., 2013)

Though US is able to detect simultaneously and at different sites different aspects of the disease, clinical application of US might be limited by the experience of the operator. However, in one study, after 1 week of disease-oriented training program, rheumatologists with limited experience in US were satisfactorily able to detect and interpret the main US signs indicative of MSU crystal deposits at different tissues in patients with gout. (Gutierrez et al., 2013)

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has a very high resolution in imaging soft tissue and bone. Although it does not involve ionizing radiation, it is expensive, time consuming and not readily available within the office setting.

Although MRI is not able to directly image MSU crystals, tophi are observed as amorphous/nodular areas of low-intensity signal on T1-weighted images, variable intensity on T2-weighted images and variable, patchy enhancement after intravenous contrast (Yu et al., 1997). Tophi may appear as discrete nodules, expanding along defined anatomic planes, or depositing in a contiguous manner (Popp et al., 1996).

MRI can also observe intra-articular features, such as synovitis, synovial hypertrophy, joint effusions and soft-tissue oedema (Cimmino et al., 2011). Of interest, even in patients without clinically apparent gouty inflammation, synovial pannus (Carter et al., 2009). Moreover, MRI is more sensitive than both CR and US in detecting bone erosions (Carter et al., 2009), and it is able to detect erosions in gout even at its first presentation (Cimmino et al., 2011).

Though MRI has the specific capability of detecting bone marrow oedema (BME), this feature is less frequently observed in gout compared with other erosive arthropathies. In patients with gout, BME is more likely to be associated with infectious complications (osteomyelitis). (Poh et al., 2011)

The ability of MRI to visualise soft-tissue including bursae, tendons and ligaments allows for detailed assessment of these structures in patients with gout, increasing the sensitivity in detecting tendinopathy, dactylitis and intratendinous tophi (Andracco et al., 2010; Poh et al., 2011).

Figure 2. Magnetic resonance imaging features of gout. (Image courtesy of Prof Marco A Cimmino).

Data on the diagnostic accuracy and responsiveness to treatment are still lacking for MRI. (Villaverde et al., 2013) Nevertheless, MRI is a good candidate imaging modality to measure tophi burden and damage over time. Moreover, MRI is clinically useful when spine involvement or complications, such as osteomyelitis, are suspected. (Poh et al., 2011)

Conventional and Dual-energy Computed Tomography

Modern multi-detector computed tomography (CT) scanners are able to quickly provide high resolution images of the peripheral areas. Despite ionising radiation are administered, the application to the extremities does not limit the application of CT in gout.

CT scan is very accurate in detecting bone disease and tophi (Gerster et al., 1996). Because of its multi-planar visualisation and resolution, CT is the gold standard technique to image bone erosion in inflammatory joint diseases (Not sure what ref 24 is: could use Døhn et al, 2006)

Conventional CT scan is not able to detect MSU crystal deposition, synovitis and BME.

The diagnostic accuracy of conventional CT for gout has not been reported to date, and its use is now limited to research or to evaluation of complications of disease, such as spinal involvement.

There is increasing interest in on dual source CT (DECT) in gout. DECT uses a specific algorithm that assigns different colours to materials of different chemical composition and has been well validated as a non-invasive method to determine the chemical composition of kidney stones. Due to its characteristics it can readily visualize MSU crystal deposition and is a good candidate to diagnose and monitor the disease.

Figure 3. Dual Energy Computed Tomography in a patient with tophaceous gout. MSU crystals are colour-coded green. (Image courtesy of Dr Nicola Dalbeth).

Several studies have evaluated the diagnostic performance of DECT in case-control diagnostic studies with sensitivity ranging from 78 to 100% and specificity from 79 to 100%. (Glazebrook et al., 2011; Choi et al., 2012, Gruber et al., 2014)

A recent study compared US and DECT showing high diagnostic performance for both imaging modalities with higher concordance of US with MSU crystal detection (Gruber et al., 2014)

As with conventional CT, DECT can also depict bone disease in gout including bone erosion, and features of new bone formation (Dalbeth et al., 2014). Its capability of detecting MSU crystal deposition may be useful in monitoring disease and in the evaluation of the response to treatments. As for conventional CT, DECT use is limited by its cost, availability and using of ionising radiation.

Conclusions

Imaging is useful to evaluate many aspects of disease in gout: inflammation, MSU deposits and damage. Different imaging modalities assist in different phases and aspects of the disease. US and DECT are the principal candidates to be applied in the diagnostic process and in monitoring long term consequences of the disease.

Connective tissue diseases: Concepts and pathogenesis, overlap syndromes, mixed CTD and undifferentiated CTD

Chiara Tani, Marta Mosca, Silvia Bellando Randone

A previous version was co-authored by Gemma Lepri, Silvia Bellando Randone, Christian Beyer, Oliver Distler, Jorge H.W. Distler

LEARNING OBJECTIVES

- Acknowledge that patients with symptoms suggestive of one or more inflammatory rheumatic diseases who do not fulfil classification criteria for a specific entity often present in daily clinical practice
- Describe and explain the prospects and limitations of classification criteria in the diagnosis of connective tissue diseases
- Apply knowledge of clinical symptoms and diagnostic findings suggestive of undifferentiated connective tissue disease, overlap syndromes and mixed connective tissue disease
- Describe and explain the course and prognosis of undifferentiated connective tissue disease, overlap syndromes and mixed connective tissue disease and their clinical warning signs for major organ involvement
- Use diagnostic screening algorithms for the individual patient depending on her/his risks for major organ involvement, such as pulmonary arterial hypertension in a patient with mixed connective tissue disease
- Apply treatment strategies for patients with undifferentiated connective tissue disease, overlap syndromes and mixed connective tissue disease depending on their disease activity and individual organ involvement
- Evaluate the limited scientific evidence for the treatment of undifferentiated connective tissue disease, overlap syndromes and mixed connective tissue disease

1 Introduction

Diagnosis of rheumatic diseases can be challenging. Many clinical signs and symptoms as well as laboratory markers are not specific for a certain rheumatic disease but may occur in different diseases. This includes Raynaud's phenomenon, arthritis, interstitial lung disease and small vessel vasculitis, as well as antinuclear antibodies (ANAs), rheumatoid factor (RF), anti-Ro/SSA and anti-La/SSB antibodies. Only a few clinical findings like scleroderma and some biomarkers, including anti-cyclic citrullinated antibodies in rheumatoid arthritis (RA), anti-Sm and anti-double-stranded DNA antibodies in systemic lupus erythematosus (SLE) and anti-topoisomerase and anticentromere antibodies in diffuse and limited systemic sclerosis (SSc), have a relatively high specificity for the corresponding disease.

Thus, 25–50% of patients referred to tertiary rheumatology centres do not carry a diagnosis of a clearly defined rheumatic disease or present with features of two or more rheumatic diseases (LeRoy et al, 1980*; Cervera et al, 1990*). These patients are classified as having either undifferentiated connective tissue disease or overlap syndrome. Mixed connective tissue disease, however, should not be confused with undifferentiated connective tissue disease or overlap syndrome. This, in fact, is a distinct clinical entity that manifests as a mixture of certain clinical features also seen in other rheumatic diseases. The following article will shed light on the subtle differences among these three rheumatic entities; it will explain the different organ manifestations and risks for severe complications; it will further demonstrate the consequences for organ screening, follow-ups and treatment of these diseases; this article will finally show why it is important to differentiate between each of these entities and separate them from other rheumatic diseases.

2 Undifferentiated connective tissue diseases

2.1 Introduction and definition

Patients who present with features of a connective tissue disease but who do not fulfil current criteria for a specific connective tissue disease are diagnosed as having 'undifferentiated connective tissue disease' (UCTD) (LeRoy et al, 1980; Mosca et al, 2014). Classification criteria for UCTD have not been defined, but there is a general consensus that the term UCTD refers to unclassifiable systemic autoimmune diseases which share clinical and serological manifestations with definite connective tissue diseases but not fulfilling any of the existing classification criteria. Some authors even add undifferentiated arthritis to the group of UCTDs. Since UCTD in significant numbers of these patients will evolve into RA, spondyloarthritis or other rheumatic diseases that do not belong to the group of connective tissue diseases, we believe that these patients should not be grouped as UCTDs. This is particularly true for patients with undifferentiated arthritis positive for anti-CCP antibodies. As many as 83% of these patients will fulfil the American College of Rheumatology (ACR) criteria for RA after 1 year and up to 93% after 3 years of follow-up (van Gaalen et al, 2004). Undifferentiated

arthritis might evolve into a defined connective tissue disease in only a minority of patients (<10%) (Wolfe et al, 1993).

2.2 Clinical features of UCTD

The definition of UCTD includes a wide spectrum of diseases that can be referred to the following scenarios with variable disease course and prognosis:

- Patients with recent onset of symptoms and unclassifiable clinical picture; in this group of patients, the undifferentiated condition better refers to a “incomplete”, “atypical” or “mild” disease presentation which is very likely to progress into a definite CTD in the short time or, sometimes, even years after symptoms onset. This group of undifferentiated conditions represents the “early phase” of a CTD and their effective recognition has a crucial clinical importance in term of treatment decision making and disease monitoring.
- Patients with “stable UCTD”, a distinct clinical entity with peculiar clinical findings; the proposed preliminary classification criteria for UCTD include at least one clinical manifestation of CTDs, positive ANA results, and disease duration of at least three years (**Mosca M, 1999**). In these patients severe organ involvements (such as renal or neurological manifestations) are only occasionally reported, the clinical picture is usually stable over time and necessitates mild therapeutic intervention (**Bodolay E, 2003 ; Mosca M, 2013, Danieli MG, 1999**)
- Patients with ‘organ-dominant’ conditions (e.g., idiopathic non-specific interstitial pneumonia) and antinuclear antibodies or other serological features or mild clinical symptoms suggesting an autoimmune process.

Typical presenting symptoms of patients with UCTD are Raynaud’s phenomenon (80%), arthralgias (60–70%), arthritis (30–40%), sicca symptoms (25%), alopecia (20%), photosensitivity (15–25%), malar rash (3–10%), sclerodactyly (10%), leucopenia (10–25%), thrombocytopenia (5–15%) and anaemia (5%) (Danieli et al, 1999; Mosca et al, 2002).

When suspecting an early form of a specific rheumatic disease that does not fulfil classification criteria, the suffixes ‘pre-’ or ‘early’ might help to distinguish this condition from a “true” (stable) UCTD. For example, patients with new-onset Raynaud’s phenomenon, typical changes detected at nailfold capillaroscopy, telangiectasias and specific antibodies for SSc, might be classified as pre- or early SSc, also according to the new ACR/EULAR classification criteria (Van den Hoogen et al, 2013). It is necessary to emphasise the importance of one of the earliest signs of many connective tissue diseases: Raynaud’s phenomenon. This may precede by several years the onset of a connective tissue disease, such as SSc, where it is considered a pivotal sign. For

this reason, a careful history and physical examination of these patients is mandatory to identify potential organ manifestations suggestive of rheumatic disease (Koenig et al, 2008).

When we encounter patients with Raynaud's phenomenon (RP) it is important to distinguish between the primary and the secondary form, and also to exclude patients with other causes of Raynaud's syndrome, such as vibration injury, drugs (eg, β blockers, ergotamines or cocaine), chemicals (eg, vinyl chloride), occlusive arterial disease and hyper viscosity syndrome. Studies have shown that after an extended screening programme during a mean follow-up of 11.2 years, the prevalence of transition from primary to secondary RP, was 14.9% of all patients (Hirschl et al, 2006). This result suggests that patients initially identified as having a primary RP should be followed up with a nailfold capillaroscopy examination in order to identify alterations of the capillary network as soon as possible. Screening of patients with SSc for ANAs and—in certain cases—for cryoglobulins will complete the basic investigation. In addition to the patient's clinical history, clinical findings (eg, severe digital ischaemia, asymmetrical attacks, later age at onset), suspicious findings on capillaroscopy and the presence of ANAs at high titres increase the probability of a rheumatic disease and reject the diagnosis of primary RP (fig. 1)

Figure 1 The concept of undifferentiated connective tissue disease. DM, dermatomyositis; MCTD, mixed connective tissue disease; PM, polymyositis; SLE, systemic lupus erythematosus; SSc, systemic sclerosis; UCTD, undifferentiated connective tissue disease.

2.3 Prognosis of UCTDs

Several large, prospective studies have examined the outcome of patients with UCTD. These studies show consistently that most patients with UCTD will have the same diagnosis even after several years of follow-up. In the remaining patients, the development of a defined rheumatological disease is more common than complete resolution of the symptoms.

In a prospective study of 143 patients with a mean follow-up of 10 years, the diagnosis of UCTD persisted in 65% (Williams et al, 1999). At the end of the follow-up, a total of 29% fulfilled the criteria for a defined rheumatic disease, most commonly SSc (15%) and SLE (13%), but also RA and mixed connective tissue disease (MCTD) (3% each). Remission of symptoms was found in only 6% of the patients. In 165 Italian patients, 82% were still classified as having UCTD after 5 years and only 6% developed defined connective tissue diseases, with SLE being most common. Twelve per cent of the patients were asymptomatic after 5 years (Danieli et al, 1999). In a Hungarian prospective study, 53% of 665 patients still carried the diagnosis of an UCTD after 5 years. A defined rheumatological disease developed in 35% of cases with 13% of patients being diagnosed with RA, 7% with Sjögren's syndrome, 4% with SLE, 4% with MCTD, 3% with SSc and <1% with polymyositis (PM) or dermatomyositis (DM). In addition, 3% of patients developed systemic vasculitis. Complete remission of clinical findings occurred in 12% of patients with UCTD (Bodolay et al, 2003).

Based on available data, several factors may be predictive for the development of SLE. These predictors include serological findings such as anti-dsDNA antibodies, anti-Sm antibodies, anticardiolipin antibodies, false-positive test for syphilis, positive Coombs test, a homogeneous ANA pattern and multiple antibody specificities. The following clinical findings are also predictive for the development of SLE: alopecia, acute or subacute skin rash, discoid lesions, serositis and cardiac complications (Alarcon et al, 1996; Mosca et al, 2002; Bodolay et al, 2003; Bortoluzzi A, 2016). Of note, anti-Sm antibodies, anticardiolipin antibodies, a homogeneous ANA pattern, discoid lesions and serositis may be the strongest predictors.

Furthermore, oesophageal dysfunction might predispose for the development of a connective tissue disease. In a study on 145 patients with UCTD, 46% were found to have oesophageal dysfunction by radionuclide oesophageal transit scintigraphy (Gaal et al, 2005). Of note, 71% of the patients with oesophageal dysfunction were asymptomatic. Pathological findings from radionuclide oesophageal transit scintigraphy predicted the development of a defined connective tissue disease.

In addition to studies investigating the outcome of patients with UCTD, in general, several studies have analysed the outcome of patients with UCTD with particular manifestations. A meta-analysis of 10 articles with a total of 639 patients concluded that a secondary connective tissue disease develops in about 13% of those patients presenting with isolated RP by an average of 10 years from its onset (Spencer-Green, 1998). The best predictor for the transition to a connective tissue disease was an abnormal nailfold capillary study demonstrating avascular areas and giant capillaries with an overall reduced capillary density. The positive predictive value for developing a connective tissue disease in a patient presenting with RP was 47%.

Isolated positive ANA testing is a poor predictor for the development of a specific connective tissue disease, with a positive predictive value of 30% (Spencer-Green, 1998). In contrast, positive ANAs together with anticentromeric staining patterns are good predictors for the development of SSc. In a small series of 46

patients with RP and one other symptom, the disease evolved into SSc in 24%. The best predictor for the development of SSc was the presence of autoantibodies with a sensitivity of 60% and a specificity of 98% in this population (Kallenberg et al, 1988; Kallenberg, 1995*).

Autoantibodies might be detectable several years before disease onset. In a study of 130 patients with SLE, at least one autoantibody was present in 88% of patients before diagnosis (Arbuckle et al, 2003*). On average, the time between the first appearance of autoantibodies and the diagnosis of SLE was 3.3 years, but the onset of disease could be delayed by up to 9.4 years. ANAs were present in 78%, anti-dsDNA antibodies in 55%, anti-Ro antibodies in 47%, anti-La antibodies in 34%, anti-Sm antibodies in 32%, anti-RNP antibodies in 26% and antiphospholipid antibodies in 18% of patients. ANAs, anti-Ro antibodies, anti-La antibodies and antiphospholipid antibodies were the first autoantibodies to appear, followed by anti-dsDNA antibodies and finally, anti-Sm and anti-RNP antibodies.

Direct comparison of mortality in patients with UCTD and other connective tissue diseases does not exist. Comparison of results from different studies, however, showed that the mortality of patients with UCTD was intermediate in comparison with other connective tissue diseases. In patients with UCTD, 5- and 10-year survival rates have been reported as 83% and 76%, respectively (Mosca et al, 2002). Two studies on patients with SLE reported survival rates of >90% after 5 and 10 years (Trager and Ward, 2001; Cervera et al, 2003). By contrast, patients with diffuse SSc have survival rates of about 63% after 7–10 years (Ferri et al, 2002; Scussell-Lonzetti et al, 2002). Nevertheless, comparability of these different studies is limited owing to several confounding factors, including patient selection, data acquisition, ethnic populations, available treatments and organ manifestations. For instance, patients with SLE-associated kidney disease or SSc-associated pulmonary arterial hypertension (PAH) had a poor prognosis, while patients with SLE and SSc with skin disease only had a relatively long survival compared with the overall survival of the disease groups of these studies.

2.4 Management of patients with UCTDs

Although most patients will continue to have a diagnosis of UCTD, they should be followed up closely since additional disease manifestations may develop, fulfilling the criteria for a defined rheumatological disease. Both new disease manifestations and the new diagnosis might change the further management of the patient. For instance, patients with accumulating symptoms suggestive of SLE need to be closely monitored for potentially life-threatening manifestations, such as glomerulonephritis. Patients with RP and anticentromere antibodies have a higher risk of developing PAH and need to be monitored by echocardiography.

Treatment of patients with UCTD usually includes antimalarial agents, low doses of steroids and symptomatic drugs depending on the presenting clinical manifestations. Treatment options derive from study results and experiences in other rheumatic diseases. We will discuss later the treatment options for patients with UCTD together with management principles in patients with MCTD.

2.5 Overlap syndromes

Overlap syndrome is often defined as an entity that satisfies the classification criteria of at least two connective tissue diseases occurring at the same time or at different times in the same patient (Iaccarino et al, 2013). Virtually any combinations of coexisting rheumatic diseases have been reported in the literature. In this chapter, we will discuss selected overlap syndromes that are particularly characteristic or very common.

Cardinal signs of one specific connective tissue disease may also be part of the normal clinical spectrum of another, since many clinical findings and laboratory markers lack specificity. For instance, myositis or myopathies may occur in a subset of patients with SSc (Pope et al, 2002). Four large studies have evaluated the SSc/myositis overlap syndrome and reported 282/633 cases; SSc/myositis seemed to be the second most common SSc overlap syndrome after SSc/RA (Balbir-Gurman et al, 2001; Caramaschi et al, 2007; Pakozdi et al, 2011; Koschik et al, 2012; Iaccarino et al, 2013). Patients with this overlap syndrome do not necessarily fulfil the classification criteria for polymyositis and might have myositis as part of the clinical spectrum of SSc. To make this issue more complicated, classification criteria are of limited value in the early diagnosis of rheumatic diseases. Therefore, patients with SSc and myositis might still have an incomplete or early form of polymyositis as well as SSc. This example highlights the challenges in the diagnosis and classification of connective tissue diseases. Similar considerations may account for many overlap syndromes. In our own clinical practice, we reserve the diagnosis of overlap syndromes for patients who clearly present with classic features of two different rheumatic diseases, including the presence of specific autoantibodies (figure 2). Nevertheless, there is no general consensus about this subject.

Figure 2 The concept of overlap syndrome. PM, polymyositis; SSc, systemic sclerosis.

2.5.1 SLE–RA overlap

Paying tribute to the name of both diseases, the overlap of RA and SLE is called ‘rhumus’ (Panush et al, 1988). The exact definition of ‘rhumus’ syndrome is still debated. In some cases it has been defined as a condition in which patients present clinical features of SLE and RA, and this hypothesis is supported by the simultaneous

presence of SLE-specific autoantibodies (anti-DNA, anti-Sm) and RA-specific autoantibodies (anti-citrullinated protein antibodies (ACPA). Rhupus seems to be as common as the chance of simultaneously having both SLE and RA (Panush et al, 1988). This supports the concept that rhupus represents the coexistence of two separate diseases in the same patient, rather than an additional disease entity. Others authors prefer to consider the 'rhupus' syndrome as an erosive subset of SLE arthropathy (Iaccarino et al, 2013).

The serological overlap between RA and SLE is well known with up to 20% of RA patients exhibiting antinuclear antibodies. However, patients with a true concomitance of RA and SLE are rare. The real prevalence, clinical picture and the natural history of this condition are documented in the literature by case series and small cohorts with significant discrepancies among case definitions and assessment methods. Indeed, in most recent studies, the reported prevalence of rhupus in SLE cohorts ranges between <1% and 17% depending on the adopted inclusion criteria and assessment methods. (Li J, 2014, Tani C, 2013, Gormezano NM, 2016)

Although erosive changes are rarely noted on plain radiographs in patients with SLE, more sensitive imaging techniques, such as magnetic resonance imaging, can disclose erosions in up to 60% of patients (Ostendorf et al, 2003; Iaccarino et al, 2013). In addition, flexion deformities, ulnar deviation, soft tissue laxity and swan neck deformities, as seen in RA, have been noted in 15–50% of patients with SLE (fig.3). (Weissman et al, 1978; Cronin, 1988; Van Vugt et al, 1998).

Recently, the characteristics of a small series of patients with rhupus identified among SLE patients were assessed from the clinical, serological and the instrumental (US and MRI) point of view; in this series arthritis was responsible for the major disease burden at the time of the evaluation; indeed, clinical signs of active synovitis and clinically detectable joint deformities were present respectively in 90% and in 60% of the cases. Interestingly, the severity of the joint disease was also highlighted by the instrumental data which revealed a high prevalence of inflammatory signs (synovial effusion, synovial hyperplasia) and severe joint damage (bone oedema and erosions). From the laboratory point of view, high levels of ESR and CRP were a clinical hallmark of rhupus patients with respect to the entire SLE cohort (Tani C, 2013).

The prevalence of ACPA in 'rhupus' patients is estimated around 57% and 100% (Amezcu-Guerra et al, 2006; Iaccarino et al, 2013) that is significantly higher than in SLE patients; moreover, some studies report a lower prevalence of these antibodies in patients with non-erosive arthritis in comparison with those with erosive disease (Chan et al, 2008; Iaccarino et al, 2013).

In patients with 'rhupus', severe SLE extra-articular manifestations (such as glomerulonephritis and neurological involvement) are less common than in patients with SLE. (Li J, 2014; Tani C et al, 2013)

Figure 3 Picture showing the left hand of a patient with rhupus. Please note that the clinical appearance is indistinguishable from RA.

Figure 4 Hand-wrist plain radiograph of a patient with rhupus. Please note extensive carpal collapse, erosions and subluxations.

2.5.2 SSc overlap syndromes (PM-SSc and RA-SSc overlap)

Symptoms of SSc can occur in combination with those of other connective tissue diseases (CTD); this condition is defined as SSc-overlap syndrome. No classification criteria for SSc-overlap syndrome are available, however, it is generally considered when musculoskeletal involvement (myositis, arthritis) or clinical signs of other rheumatic diseases are substantially greater than usually found in SSc patients (Pakozdi A, 2011). It is reported that up to 20% of patients with SSc have overlapping features with other rheumatologic diseases, being polymyositis/dermatomyositis (43%) and rheumatoid arthritis (32%) the most frequently reported (Pakozdi A, 2011)

Recently, 10% of SSc-overlap syndromes have been identified among the 3240 SSc patients registered in the database of the German Network for Systemic Scleroderma and prospectively followed between 2003 and 2013; interestingly, these subgroup of patients showed distinct serological and clinical profile with respect to the rest of cohort thus supporting the concept that SSc-overlap syndromes should be regarded as a separate SSc subset, distinct from both the limited and the diffuse cutaneous SSc. (Moinzadeh P, 2015)

Autoantibodies are helpful to separate SSc-overlap syndromes from other SSc subsets. In particular, two distinct autoantibody specificities have been associated with the PM-SSc overlap. However, these antibodies can also be found in other connective tissue diseases or overlap syndrome in 17% of cases (Jablonska and Blaszyk, 2004; Iaccarino et al, 2013). In the study of Pakozdi et al, anti-PM-Scl antibodies were found in 33.1% of the patients with SSc/myositis (Pakozdi et al, 2011). In the United States, anti-PM-Scl antibodies are significantly more common in patients with PM-SSc overlap (Targoff et al, 1992). This association could not be confirmed in a Japanese population. By contrast, anti-Ku antibodies were predictive of PM-SSc overlap in the Japanese study population. The differences between the American and the Japanese study might be—at least in part—explained by different frequencies of HLA-DR3 in the two populations, since the genotype is closely associated with anti-PM-Scl antibodies (Ioannou et al, 1999). Other studies showed a prevalence of anti-Ku antibodies in patients with PM-SSc, ranging from 2.3% to 55% (Cavazzana et al, 2008; Belizca et al, 2010; Pakozdi et al, 2011).

Inflammatory joint involvement is another frequent manifestation in patients with SSc-overlap syndromes. These patients are often identified by typical SSc-clinical symptoms (usually limited skin involvement) together with high titers of anticyclic citrullinated peptides (ACPA) and/or higher rheumatoid factor (Ueda-Hayakawa M, 2010, Szucs G, 2007)

Among all patients with SSc, ACPA positivity has been reported in 1.7–14.8% (Avouac et al, 2006; Szucs et al, 2007; Iaccarino et al, 2013). In these patients, ACPA were strongly associated with erosions detected by X-ray examination or with arthritis. In the study by Szucs et al the metacarpophalangeal, carpal, proximal interphalangeal joints and the ulnar heads were found to be more frequently affected by arthritis in patients

with SSc–RA. Most of these subjects had a limited SSc. The extra-articular manifestations included RP, present in 100% of patients, and pulmonary fibrosis, present in 77.3% (Iaccarino et al, 2013).

Overlap-syndrome management

Patients with overlap syndromes are treated according to study protocols and experience with the underlying rheumatic diseases and mainly based on the type of organ involvement. Owing to small patient numbers and poor definition of overlap syndromes, randomized controlled trials have not been performed, and separate guidelines for the treatment of overlap syndromes have not been established.

3 Mixed connective tissue disease

3.1 Introduction

Although the terminology might be misleading, MCTD (formerly, Sharp's syndrome) is a distinct rheumatic disorder. Sharp and colleagues first described the disease in 1972 as a connective tissue disease with features of SLE, SSc and polymyositis. High titres of anti-U1-RNP autoantibodies further defined this disease (Sharp et al, 1972*; Tani et al, 2014). Later, a high prevalence for the development of arthritis resembling the RA joint pattern was seen in patients with MCTD (figure 5).

Figure 5 The concept of mixed connective tissue disease. *MCTD, mixed connective tissue disease; PM, polymyositis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SSc, systemic sclerosis.*

The clinical features of MCTD often develop over several years and the complete clinical findings are rarely present at the start of the disease. In early stages, patients often present with one of the following features: Raynaud's phenomenon, puffy fingers of the hands (figure 4), sclerodactyly, arthralgias, arthritis, myalgias, myositis and malaise. These clinical features are the most frequently reported in the different cohorts during the course of the disease, together with lung involvement and oesophageal symptoms (Tani et al, 2014).

Figure 6 Swollen fingers.

Mixed connective tissue disease is rare with a prevalence of 3.8 per 100 000 adults (as assessed in a Norwegian population). There is a female predominance with a male to female ratio of about 1:3 (Gunnarsson et al, 2011).

3.2 Mixed connective tissue disease: a distinct disease entity?

Since the initial description, several authors challenged the concept of MCTD as a distinct clinical entity for the following reasons (Smolen and Steiner, 1998*): First, most patients diagnosed as MCTD also satisfy the criteria for another connective tissue disease, especially in later stages of the disease. Second, there are not any commonly classification criteria for MCTD, although several criteria sets have been tested successfully. Third, the initial description of MCTD as a benign connective tissue disease not involving major organ systems and promptly responding to low-dose glucocorticoids has not been confirmed by other studies.

Several genetic, serological and clinical features, however, argue for MCTD as an distinct rheumatic disease and against the concept of an early form of other connective tissue diseases such as SLE, SSc, PM or RA: MCTD is associated with HLA-DR1, HLA-DR4 and to a lesser degree with HLA-DR2 (Black et al, 1988; Kaneoka et al, 1992). In contrast, SLE is associated with HLA-DR2 and HLA-DR3, SSc with HLA-DR3 and HLA-DR5 and PM with HLA-DR3. The linkage disequilibrium and the association with different HLA class II molecules argues for MCTD being distinct from SLE, SSc and PM. Similar to MCTD, RA is associated with HLA-DR1 and HLA-DR4. Apart from erosive arthritis, however, RA barely shares clinical features with MCTD and usually does not show autoantibodies against U1-snRNP.

Serological features also support the concept of MCTD as a distinct disease entity. Although 20–30% patients with SLE might also express anti-U1-snRNP antibodies, per definition a sine qua non for the diagnosis of MCTD,

high titres of these antibodies are specific for patients with MCTD (Habets et al, 1985). Furthermore, SLE patients with anti-U1-snRNP antibodies often retain IgM-U1-snRNP, instead of showing a class switch to IgG antibodies as found in MCTD (Vlachoyiannopoulos et al, 1996). Finally, anti-U1-RNP antibodies in patients with SLE seem to differ from those in patients with MCTD by their antigen recognition (Barakat et al, 1991). Thus, high titres of IgG-autoantibodies against U1-snRNP seem to be specific for MCTD.

In addition to genetic and serological differences, certain clinical manifestations are also unique for patients with high titres of anti-U1-snRNP antibodies. Patients with high titres of antibodies against U1-snRNP rarely develop severe CNS (eg, psychosis, seizures or diffuse) or renal manifestations (eg, diffuse proliferative glomerulonephritis). By contrast, they develop RF-positive, erosive arthritis more frequently. Furthermore, they are more likely to develop pulmonary arterial hypertension than patients with other connective tissue diseases except for SSc. Thus, we agree with many other experts that MCTD is a distinct clinical entity based upon genetic, serologic and clinical features (table 1).

Table 1 Mixed connective tissue disease (MCTD) as a distinct disease entity?

MCTD as a distinct disease entity?	
Pro	Contra
<ul style="list-style-type: none"> • Association with certain HLA types • High titres of anti-U1-RNP IgG autoantibodies with unique antigen recognition • Specific set of clinical manifestations 	<ul style="list-style-type: none"> • Patients might satisfy the classification criteria of other connective tissue diseases in later stages of the disease • Not one commonly accepted set of criteria

3.3 Anti-U1-RNP antibodies

MCTD was initially described as a connective disease with high titres of autoantibodies directed against a complex named 'ribonuclease-sensitive extractable nuclear antigen'. Further studies showed that the U1-RNP particle is a major component of the spliceosome, which is a nuclear particle processing pre-messenger RNA (mRNA) splicing into mRNA (Routsias et al, 2010). Different parts of the spliceosome represent targets of autoimmunity in several connective tissue diseases. The immunogenic potential of spliceosomal components may be increased by post-translational modifications during apoptosis (Mamula et al, 1999).

The small nuclear ribonucleoprotein particles (snRNPs) and the heterogeneous nuclear ribonucleoprotein particles (hnRNPs), two spliceosomal subunits, are the major targets of autoimmunity. SnRNPs contain small RNAs ranging from 80 to 350 nucleotides complexed with proteins. U1-RNPs are a subset of snRNPs with high amounts of uridine nucleotides (called U1-RNA). The U1-RNA molecules form double-stranded secondary structures, which make up the backbone of the U1-RNP complex. The protein components of the U1-RNP complex can be further classified into proteins specific for the U1-RNP complex and non-specific proteins.

Specific proteins are U1-A, U1-C and U1 68 kDa proteins. Non-specific proteins include the Smith proteins (Sm proteins) and the SR proteins, a group of splicing factors rich in serine (S) and arginine (R). Autoantibodies against U1-RNP and other snRNPs mainly recognise the protein components of the complex. Sm proteins are common targets of autoimmunity in SLE, whereas patients with MCTD usually have high antibody titres for the U1 68 kDa protein (Fenning et al, 1995).

hnRNPs contain pre-mRNAs and a variety of structurally related proteins with molecular weights between 33 and 43 kDa. Anti-RA33 antibodies target 33 kDa hnRNP-A2 proteins of the hnRNP complex. Raised titres of anti-hnRNP-A2 antibodies are present in about 30% of patients with RA, SLE and MCTD. The antigen recognition pattern in MCTD, however, differs from that of RA and SLE (Smolen and Steiner, 1998*).

In an animal model of MCTD, mice expressing the HLA-DR4 molecule (HLA-DRA*0101/DRB1*0401) develop anti-U1-RNP antibodies after a single exposure to the 70 kDa polypeptide/U1-RNA autoantigen. Clinically, these mice develop pulmonary inflammatory infiltrates characteristic of MCTD. They do not develop anti-Sm or anti-DNA antibodies, which distinguishes the model from SLE (Greidinger et al, 2008).

Molecular mimicry may lead to the development of anti-U1-RNP antibodies. This hypothesis suggests the presence of antigens (eg, infectious agents) that closely resemble the U1-RNPs and cause the production of cross-reactive antibodies. While the exogenous antigen might be cleared over time, the immune reaction against the endogenous U1-RNP structures might persist. Although some evidence for the role of molecular mimicry in connective tissue disease exists, including associations of Epstein–Barr virus with anti-Sm antibodies, and cytomegalovirus with anti-U1 68 kDa antibodies (McClain et al, 2003; Newkirk et al, 2001), it still needs further scientific proof.

Apart from anti-U1-RNP antibodies, a variety of other antibody specificities, may be present in patients with MCTD; in a recent study, Anti-Ro52 antibodies were present in 29%, anti-Ro60 in 19% and anti-SSB in 6% of the MCTD sera. Interestingly, anti-Ro52 antibodies were significantly associated with lung fibrosis (Gunnarsson R, 2016).

Antigen spreading to molecules in close proximity to the original antigen (ie, the U1-RNP complex) may play a role. Nevertheless, several antigens do not show structural homologies or colocalize with the U1-RNP complex. In these cases, defective clearance of apoptotic material with a high immunogenic potential, might lead to the formation of antibodies against other antigens (Rosen and Casciola-Rosen, 2001). Ro/SSA antigens, for example, occur in high concentrations on apoptotic blebs. Incomplete B or T cell tolerance to apoptotically modified antigens might also be of importance (Casciola-Rosen et al, 1999).

Although anti-U1-RNP antibodies are a sine qua non for the diagnosis of MCTD, their role in the pathogenesis of MCTD is unclear. In this context, recent data from an animal model suggest that anti-U1-RNP antibodies can

mediate tissue injury (Provost et al, 1987; Mason et al, 2004). Mice immunized with apoptotically modified U1 68 kDa proteins developed a MCTD-like interstitial lung disease, whereas mice immunized with control antigens did not. This animal model is of interest because a diversifying autoimmune response is seen in response to immunization with apoptotically modified U1 68 kDa proteins. In addition to antibodies against the exogenous U1 68 kDa protein complex, these animals also show antibody formation against epitopes on endogenous U1 68 kDa proteins and non-U1-RNP proteins. This mimics, at least in part, the situation in human MCTD.

3.4 Sequential clinical and laboratory features of patients with anti-U1-RNP antibodies

MCTD evolves over time and patients typically develop new clinical and laboratory features in the course of the disease. Thus, patients might display few features of the disease and may not fulfil the classification criteria for MCTD at their initial presentation. Furthermore, patients with antibodies against U1-RNP might meet the classification criteria for rheumatic diseases other than MCTD (Reichlin, 1976*; Habets et al, 1985).

In the first prospective study on patients with anti-U1-RNP antibodies, 60% of patients presented with symptoms compatible with a specific connective tissue disease other than MCTD. After a mean follow-up of 6 years, however, 90% fulfilled the criteria for MCTD (Sullivan et al, 1984*).

At the start of another study of 32 patients with high- and low-titer anti-U1-RNP antibodies, only three patients fulfilled the classification criteria for MCTD and 11 patients for other connective tissue diseases. The remaining 18 patients were classified as having UCTD. After a mean observation period of 6 years, 15 of the 18 patients (83%) initially diagnosed with UCTD met the classification criteria for specific connective tissue diseases: 11 for MCTD, two for SLE and two for both MCTD and SLE (Lundberg et al, 1991b).

Diagnosis of other rheumatic diseases (in particular, UCTD) may evolve into a diagnosis of MCTD over time. The initial diagnosis of MCTD may also change into the diagnosis of another rheumatic disease. In a study on 46 patients positive for anti-U1-RNP antibodies, 33 were classified with MCTD, 10 were diagnosed with SLE, two with RA and one with SSc (Van den Hoogen et al, 1994). After 5 years, 55% of the patients initially diagnosed with MCTD fulfilled the classification criteria for another connective tissue disease. Twenty-one per cent developed SSc, 15% SLE, 9% RA and 9% an overlap syndrome. Of the 10 patients in this study, who fulfilled the criteria for SLE at the initial presentation, four developed clinical SSc features. In a recent retrospective study, 161 patients had initially been diagnosed as having MCTD by three different sets of classification criteria (Sharp, Alarcon-Segovia and Kasukawa (discussed in detail in the next section)). After a mean follow-up of 7.9 years, 57.9% of patients still had the diagnosis of MCTD. By then, the other patients carried a diagnosis of SSc (17.3%), SLE (9.1%), RA (2.5%), UCTD (11.5%) and overlap syndrome (1.7%).

Interestingly, the presence of autoantibodies and specific clinical features helped to predict the evolution into

another rheumatic disease: the presence of anti-dsDNA antibodies was associated with evolution into SLE, hypomotility or dilatation of the oesophagus and sclerodactyly with evolution into SSc (Cappelli et al, 2011).

3.5 Proposed classification criteria for MCTD

For MCTD, there is not one widely accepted set of classification criteria. Four different sets of classification criteria for MCTD are available—namely, the criteria of Sharp, Alarcon-Segovia, Kahn and Kasukawa (Alarcon-Segovia and Villareal, 1987; Kasukawa et al, 1987; Sharp, 1987; Kahn, 1991). Since none of those criteria is convincingly better than the others, all four sets of criteria may be used.

Sharp's criteria consist of five major and 11 minor criteria to distinguish between definite MCTD and probable MCTD (table 2). In contrast to the three other sets of criteria, Sharp's criteria do not demand the presence of high titres of U1-RNP antibodies for the diagnosis of MCTD. According to Sharp, a patient can have probable MCTD in the absence of anti-U1-RNP antibodies. Nevertheless, for the diagnosis of definite MCTD, anti-U1-RNP antibodies are necessary.

Table 2 Sharp's criteria for mixed connective tissue disease

Major criteria	Minor criteria
1. Severe myositis	1. Alopecia
2. Lung involvement with a TLCO <70% and/or PAH and/or proliferative vascular lesions on biopsy	2. Leucopenia
3. Raynaud's phenomenon and/or oesophageal hypomotility	3. Anaemia
4. Swollen hands and/or sclerodactyly	4. Pleuritis
5. anti-ENA \geq 1:10 000, positive for anti-U1-RNP antibodies and negative for anti-Sm antibodies	5. Pericarditis
	6. Arthritis
	7. Trigeminal neuralgia
	8. Malar rash
	9. Thrombocytopenia
	10. Mild myositis
	11. History of swollen hands

- Definite MCTD: four major criteria, no anti-Sm antibodies, anti-U1-RNP antibodies >1:4000
- Probable MCTD: three major criteria and no anti-Sm antibodies or two major criteria plus one minor criterion plus anti-U1-RNP antibodies >1:1000

ENA, extractable nuclear antigen; PAH, pulmonary arterial hypertension; RNP, ribonucleoprotein; TLCO, carbon monoxide transfer factor.

Table 3 Alarcon–Segovia’s criteria for mixed connective tissue disease

Clinical criteria	Serological criterion
<ol style="list-style-type: none"> 1. Swollen hands 2. Acrosclerosis with or without proximal SSc 3. Raynaud’s phenomenon 4. Myositis: biologically or histologically proved 5. Synovitis 	Anti-RNP antibodies with a titre of >1:1600 at the haemagglutinin assay
Diagnosis of MCTD, if the serological criterion is present and three or more clinical criteria (if 1, 2 and 3 are present, 4 and 5 are also required to distinguish MCTD from SSc)	

MCTD, mixed connective tissue disease; RNP, ribonucleoprotein; SSc, systemic sclerosis.

Kahn’s criteria (table 4) are similar to those of Alarcon-Segovia. Besides the presence of high titres of anti-RNP antibodies, four clinical criteria are included.

Table 4 Kahn’s criteria for mixed connective tissue disease

Clinical criteria	Serological criterion
<ol style="list-style-type: none"> 1. Raynaud’s phenomenon 2. Swollen fingers 3. Myositis 4. Synovitis 	High titres of anti-RNP antibodies, corresponding to a speckled ANA titre of $\geq 1:2000$
Diagnosis of MCTD, if the serological criterion is present plus Raynaud’s phenomenon plus two or all of the other three clinical criteria	

ANA, antinuclear antibodies; MCTD, mixed connective tissue disease; RNP, ribonucleoprotein.

Kasukawa’s criteria (table 5) include anti-snRNP antibodies, as well as common clinical symptoms and features of the defined connective tissue diseases SLE, SSc and PM.

Table 5 Kasukawa’s criteria for mixed connective tissue disease

Common symptoms	Symptoms of SLE, SSc and PM	Serological criterion
<ol style="list-style-type: none"> 1. Raynaud’s phenomenon 2. Swollen fingers 	<p>SLE:</p> <ol style="list-style-type: none"> 1. polyarthritis 2. adenopathies 3. malar rash 4. serositis 5. leucopenia and/or thrombocytopenia <p>SSc:</p> <ol style="list-style-type: none"> 1. sclerodactyly 2. pulmonary fibrosis and/or restrictive changes and/or reduced TLCO 3. oesophageal hypomobility or dilatation <p>PM:</p> <ol style="list-style-type: none"> 1. muscle weakness 2. raised muscle enzymes 3. myogenic changes in EMG 	anti-snRNP antibodies

Diagnosis of MCTD, if one or two common symptoms plus one or more symptom of the mentioned signs of two or three of the defined connective tissue diseases SLE, SSc and PM plus the serological criterion

EMG, electromyogram; MCTD, mixed connective tissue disease; PM, polymyositis; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; SSc, systemic sclerosis; TLCO, carbon monoxide transfer factor.

Sharp's, Alarcon-Segovia's and Kasukawa's criteria have been tested for their specificity by applying them to patients with other rheumatic diseases, including SLE, RA, SSc, DM/PM and Sjögren's syndrome (Alarcon-Segovia and Cardiel, 1989). These studies were limited by the lack of a commonly accepted, typical clinical presentation of patients with MCTD to test the criteria. Alarcon-Segovia's and Kasukawa's criteria both had a very high specificity for patients with MCTD. Only one of 200 patients with SLE was diagnosed as having MCTD according to Alarcon-Segovia's criteria and none according to Kasukawa's criteria. According to these two sets of criteria, none of the patients with RA, SSc and DM/PM was diagnosed with MCTD. Finally, one of 80 patients with Sjögren's syndrome was positive for MCTD according to the Alarcon-Segovia and Kasukawa criteria.

The specificity of Sharp's criteria, however, was significantly lower and several patients were falsely identified as having probable MCTD. Sharp's criteria distinguished patients with RA and Sjögren's syndrome well (100% and 96%, respectively), but was less accurate for patients with SLE, DM/PM and, in particular, SSc (88%, 84% and 55%, respectively). Of 80 patients with high anti-RNP antibody titres with the genuine diagnosis of MCTD, Sharp's criteria and Alarcon-Segovia's criteria had a sensitivity of 100%. Using Kasukawa's criteria, two of the 80 patients were not identified (Alarcon-Segovia and Cardiel, 1989).

In another comparative study of the four classification criteria evaluating 45 patients with anti-U1-RNP antibodies, the criteria by Alarcon-Segovia and Kahn performed best (Amigues et al, 1996). Twenty-five of the 45 patients included in the study had other rheumatological diseases such as SLE, RA, SSc or overlap syndromes. Sixty-four per cent of the patients with anti-U1-RNP antibodies fulfilled Sharp's criteria, 42% those of Kasukawa and 14% each those of Alarcon-Segovia and Kahn. Of the 25 patients with other rheumatic diseases, 56% also fulfilled Sharp's criteria, 40% Kasukawa's and 14% each Alarcon-Segovia's and Kahn' criteria.

Except for Sharp's criteria, the diagnosis of MCTD depends on high titres of anti-U1-RNP antibodies. Thus, the method of detection and the cut-off point between high and low titres should be well defined. Several methods are used to measure the titres of U1-RNP antibodies but a defined cut-off value is lacking (Venables, 2006). In early studies, the haemagglutinin assay was the standard test. Other assays used are immunodiffusion, immunoblotting and immunoprecipitation. Nowadays, enzyme-linked immunosorbent assays with cloned antigens as standards are widely used.

3.6 Clinical manifestations of MCTD

The first clinical symptoms of MCTD are usually non-specific. At this stage of the disease, patients often have malaise, myalgias, arthralgias, Raynaud's phenomenon and low-grade fever. In later stages of the disease, a set of five cardinal signs should lead to the suspicion of MCTD:

- the presence of high titres of anti-U1-RNP autoantibodies—in particular, IgG antibodies that recognise the 68 kDa protein of the U1-RNP complex;
- the lack of severe kidney and central nervous system (CNS) involvement;
- severe arthritis and the presence of RF;
- pulmonary arterial hypertension;
- Raynaud's phenomenon in association with puffy hands.

Apart from these classic manifestations, almost any other organ system may be affected (Sharp et al, 1972*; Bennett and O'Connell, 1980; Alarcon-Segovia, 1994), including the vascular system, skin, gastrointestinal tract, musculoskeletal system, lungs, heart, haematological system, kidneys and CNS. Table 6 compares the clinical features of patients with UCTD and MCTD at presentation and after 5 years of follow-up.

3.6.1 Musculoskeletal manifestations of MCTD

In MCTD, joint involvement may vary from mild arthralgias to severe arthritis in small or large joints that sometimes may lead to erosions typical of RA and to mutilating arthritis (Ortega-Hernandez and Shoenfeld, 2012). As described above, the joint involvement in MCTD tends to be more severe than in SLE and SSc. Inflammatory arthritis is a frequent presenting symptom of MCTD and occurs in 60–100% of patients. Most commonly, joint involvement is present in a RA-like pattern with symmetrical, polyarticular involvement of the small joints of the hands and feet. As with RA, mono- or oligoarticular presentations can also occur (Piirainen, 1990). The arthritis in patients with MCTD is erosive in 30–70% of cases as shown by X-ray examination. In patients with MCTD, RF is a risk factor for erosive joint disease (O'Connell et al, 1977; Udoff et al, 1977; Bennett and O'Connell, 1980). Periarticular osteopenia, subchondral cysts and subluxations are also common. In addition, swan neck deformities and boutonniere changes are seen in up to 30% of affected patients.

Another very common feature, which might occur in up to 60% of patients, is resorption of the digital tuft. Arthritis mutilans can occur in rare cases. Non-erosive Jaccoud's arthropathy and atlantoaxial subluxation may be present in single cases (Alarcon-Segovia and Uribe-Uribe, 1979; Bennett and O'Connell, 1980; Catoggio et al, 1983; Piette et al, 1988). Nevertheless, despite the close resemblance to joint disease in RA, the course of MCTD-associated arthritis is more benign than in erosive RA, with erosions being small and scattered even after several years of active arthritis.

Between 80% and 90% of patients with MCTD develop muscle involvement, with proximal muscles being more frequently involved (Ortega-Hernandez and Shoenfeld, 2012). The prevalence of myositis in MCTD varies from 15% to 75% in different studies. This considerable variation might be explained by differences in the diagnostic methods. Myositis is often present early in the course of the disease. The clinical presentation is identical to that of other inflammatory myopathies. Most patients show weakness of the proximal muscles of the

shoulders and pelvic girdle and little if any wasting. Focal myopathies, however, have been reported in single cases. Diaphragmatic dysfunction and dysphagia due to myositis can occur, but are rare.

Table 6 Comparison of the clinical features of mixed connective tissue disease and undifferentiated connective tissue disease. Modified from Swanton and Isenberg (2005)

	MCTD (Burd et al, 1999)		UCTD (Danieli et al, 1999; Bodolay et al, 2003)	
	At the time of diagnosis (%)	Cumulative findings after 5 years (%)	At the time of diagnosis (%)	5 Years after the diagnosis (%)
Raynaud's disease	89	96	50–60	89

*Functional test performed on all patients, including asymptomatic patients.

†No functional tests performed in asymptomatic patients.

MCTD, mixed connective tissue disease; PAH, pulmonary arterial hypertension; TLCO, carbon monoxide transfer factor; UCTD, undifferentiated connective tissue disease.

On histological examination, patients with MCTD-associated myositis show histological findings similar to those of patients with PM or SLE (Ortega-Hernandez and Shoenfeld, 2012), or perivascular and endomysial lymphocytic infiltrates, similar to the histological findings in DM (Cooke and Lurie, 1977; Bennett and O'Connell, 1980). Myositis in patients with MCTD commonly manifests as acute flares and can be associated with high-grade fever. Less often, myositis presents as a smouldering process. Several case studies report myasthenia gravis in patients with MCTD, suggesting that there might be some association between these two diseases (Yasuda et al, 1993).

3.6.2 Vascular manifestations of MCTD

The majority of patients with MCTD display vascular changes (Grader-Beck and Wigley, 2005). About 75–90% of patients have Raynaud's phenomenon, which may precede the appearance of other clinical manifestations by years (Sharp et al, 1972*; Ortega-Hernandez and Shoenfeld, 2012). In addition, microvascular changes, similar to those seen in patients with SSc occur. Typical SSc-like findings of MCTD on nailfold capillaroscopy, such as avascular fields, micro-haemorrhages, bushy capillaries and giant capillaries with a general reduction of the capillary density and reduced blood flow, are present in 54% of patients with MCTD (Blockmans et al, 1993). Furthermore, Hejas et al observed a capillaroscopic 'scleroderma pattern' in 31.4% of patients at the time of diagnosis and in 40.3% after a mean of 13.1 years of follow-up, with significant progression of microvascular alterations (Hejas et al, 2013). In addition to changes of the capillaries, small and medium-sized arteries often show signs of occlusion on arteriographic studies. These occlusions, however, are asymptomatic in most cases. Interestingly, an imbalance of angiogenic and angiostatic factors reflects the capillaroscopic alterations in both MCTD and SSc, although there appear to be differences in the expression profiles of these two diseases. In MCTD, levels of vascular endothelial growth factor (VEGF) were higher in patients with PAH, acrosclerosis and myositis, suggesting that VEGF levels might help to predict the development of these disease manifestations (Distler et al, 2011).

A severe vascular manifestation of MCTD is PAH. Patients with PAH show a pulmonary artery pressure of >25 mm Hg at rest and pulmonary capillary wedge pressure <15 mm Hg, as tested by right-heart catheterisation (Simonneau et al, 2009). PAH is seen in 20–30% of patients with MCTD (Burdett et al, 1999) and the presence of anticardiolipin antibodies is associated with its development. In addition, a higher prevalence of anti-endothelial cell antibodies was found in patients with MCTD plus PAH than in those patients with MCTD but no PAH (Vegh et al, 2006). In a recent follow-up study of patients with MCTD, PAH developed in 17.8% of patients at a mean of 14.5 ± 3.71 years after diagnosis. All these patients showed a continuously high level of anti-RNP and 84% of them were positive for anti-endothelial cell antibodies (Hejas et al, 2013).

In contrast to other forms of pulmonary hypertension, which might occur in patients with MCTD, PAH is characterised by hypertrophy of the intima and proliferation of smooth muscle cells in small pulmonary arteries and arterioles, leading to a reduction of the vascular lumen. Since PAH is the major cause of death in MCTD, regular evaluation for PAH is essential. Patients with PAH usually present with a history of progressive dyspnoea on exertion. Many other clinical symptoms and signs are suggestive of PAH but are not always present.

Physical examination may disclose an accentuated second pulmonary heart sound and might also show a systolic pulsation at the left sternal border. Chest X-ray examination may demonstrate a dilatation of the pulmonary arteries and right atrial enlargement and ventricular hypertrophy. Similarly, signs of right atrial and

ventricular hypertrophy may be seen on electrocardiography. The sensitivity and specificity of chest X-ray examination and electrocardiography, however, are relatively poor; the PAH-related findings often occur late, after haemodynamic changes are already established.

Screening tests for patients at risk, however, need to detect PAH at earlier stages. Transthoracic echocardiography is becoming the first choice for PAH screening. Despite the need for a highly experienced sonographer, echocardiography is a non-invasive, cheap and feasible screening test. Transthoracic echocardiography may be inaccurate in patients with borderline or slightly raised pulmonary pressure, resulting in both false-negative and false-positive results. Serum biomarkers, such as pro-brain-type natriuretic peptide (pro-BNP), may help to increase sensitivity of echocardiographic PAH screening (Allanore et al, 2003). A Delphi consensus study has detected the tests that may lead to a suspicion of PAH in patients with SSc. Additionally, N-terminal pro-BNP and echocardiography, and also pulmonary function tests, may provide additional information, as a decrease of the carbon monoxide transfer factor (TLCO) of <50% in the absence of pulmonary fibrosis may suggest that right heart catheterisation should be carried out. There is general consensus that a suspicion of PAH needs verification by right heart catheterisation, which is the diagnostic 'gold standard' (Avouac et al, 2014).

In the study of Khanna et al, new recommendations for screening and detection of PAH associated with connective tissue disease, in particular SSc and connective tissue diseases with scleroderma features, have been published. According to these recommendations, patients should be evaluated with pulmonary function tests (including TLCO), transthoracic echocardiography and N-terminal pro-BNP initially and at least once a year thereafter. If patients have new signs or symptoms, complete screening needs to be repeated (Khanna et al, 2013).

3.6.3 Pulmonary manifestations of MCTD

A significant number of patients with MCTD have a pulmonary involvement. However, in most patients with MCTD, pulmonary changes are mild and many patients are asymptomatic (Bodolay et al, 2005). PAH, a severe complication of the disease, is the major cause of death in patients with MCTD. Apart from PAH, pleural effusions and interstitial lung disease (non-specific interstitial pneumonia or usual interstitial pneumonia pattern) are also common in MCTD. The prevalence of interstitial lung disease may be as high as 67% based on high-resolution computed tomography (HRCT) and DTPA scans (Black and Isenberg, 1992). Applying strict HRCT-based diagnostic criteria, 35 of the patients in the Norwegian nationwide MCTD cohort showed reticular patterns consistent with lung fibrosis. Lung fibrosis was quantified as minor in seven, moderate in nine and severe in 19 of all patients. Mortality was significantly increased in patients with severe lung fibrosis compared with patients with normal HRCT findings (20.8 vs 3.3 during a 4.2 years' follow-up) (Gunnarsson et al, 2012).

Reductions of the transfer factor for carbon monoxide are the most common abnormality in lung function tests (Black and Isenberg, 1992). Most patients with this abnormal finding, however, are asymptomatic and only a minority have exertional dyspnoea. Pleural disease is found in up to 40% of patients with MCTD. It can manifest as pleural effusion and pleural thickening. As with interstitial lung disease, pleural involvement is often asymptomatic. Rare pulmonary manifestations of MCTD are diaphragmatic dysfunction, alveolar haemorrhage, pulmonary vasculitis and thromboembolic disease. Table 7 summarizes the pulmonary manifestations of MCTD.

Table 7 Overview of the pulmonary manifestations of mixed connective tissue disease

Common manifestations	Rare manifestations
Interstitial lung disease	Diaphragmatic dysfunction
Pleural effusion	Alveolar haemorrhage
Pulmonary arterial hypertension	Pulmonary vasculitis
	Thromboembolic disease
	Aspiration pneumonia

3.6.4 Mucocutaneous manifestations of MCTD

Patients with cutaneous involvement often present with typical SSc- or SLE-like skin manifestations (Sharp et al, 1972*; Baurle and Hornstein, 1979; Magro et al, 1997; Sen et al, 2014). Swollen digits or oedema of the entire hands, also known as puffy hands, are a common feature of MCTD and are often the presenting signs of the disease. These findings can also occur during the early course of SSc. Other common features of both diseases are sclerodactyly and calcinosis cutis. In contrast, truncal skin fibrosis does not usually occur in MCTD. Patients might also develop digital ulcers and gangrene due to severe Raynaud's phenomenon or telangiectasias. SLE-like manifestations of MCTD include discoid plaques, subacute lupoid skin changes, photosensitivity and malar rashes, which can be indistinguishable from SLE. A recent study, evaluating cutaneous manifestations in 23 patients who fulfilled the Alarcon-Segovia and Villareal criteria, showed that five patients presented malar rash (21.7%) and two patients had discoid lupus erythematosus. Acrosclerosis and hand oedema were identified as the commonest cutaneous features (in 17 and nine patients, respectively) (Sen et al, 2014). Besides SSc- and SLE-like features, livedo reticularis, livedo vasculitis and cutaneous leucocytoclastic vasculitis have been described. Manifestations of MCTD at the mucosal membranes, which occur in a small percentage of patients, are oral and genital ulcerations and nasal septum perforation.

MCTD often overlaps with, or may reflect, features of Sjögren's syndrome. Forty per cent to 95% of patients with MCTD have sicca symptoms, including dry eyes, dry mouth and salivary or lachrymal gland inflammation. Many of these patients are positive for anti-Ro/SSA and some also for anti-La/SSB (Alarcon-Segovia 1976; Helenius et al, 2001; Setty et al, 2002).

3.6.5 Gastrointestinal manifestations of MCTD

Oesophageal hypomotility is found in 45–85% of patients with MCTD and initially it is often subclinical. As for SSc, oesophageal manometry and barium swallow can demonstrate a reduction of the peristalsis, particularly in the lower third, and a decline of the lower sphincter pressure. Consequently, patients have gastro-oesophageal reflux and might have swallowing problems in later stages. Nevertheless, oesophageal manifestations may be less severe in MCTD than in SSc. One study compared the lower oesophageal sphincter pressure in patients with MCTD and SSc. The prevalence of oesophageal involvement was similar in SSc and MCTD, but the lower oesophageal sphincter pressure in patients with MCTD was higher than in patients with SSc (Doria et al, 1991).

Besides the oesophagus, disturbed peristalsis might also occur in other parts of the gastrointestinal tract. Delayed gastric emptying was noted in 6% of patients and up to 75% of patients in one study had abnormal findings in a small bowel series, including slow transit and dilatation. Malabsorption might occur owing to bacterial overgrowth and small bowel dilatation. Pseudo-diverticula and colonic perforation are also found with increased frequency in patients with MCTD. Rare gastrointestinal manifestations that can be associated with MCTD are serositis, protein losing enteropathy, mesenteric vasculitis, Budd–Chiari syndrome, autoimmune hepatitis, primary biliary cirrhosis and pancreatitis (Marshall et al, 1990; Weston et al, 1998).

3.6.6 Cardiac manifestations of MCTD

Cardiac disease may occur in 20–30% of patients (Dutschmann et al, 1989; Smolen and Steiner, 1998*). Pericarditis is the most common manifestation, but is often mild (Lundberg et al, 2005). A recent review including 616 patients showed that the prevalence of cardiac involvement varies from 13% to 65% according to patient selection and method used for its detection. However, it highlighted that pericarditis was the most common cardiac diagnosis, with a prevalence ranging from 30% to 43% in two prospective studies (Patampong et al, 2014). In MCTD mitral valve prolapse (in up to 25%) and conduction defects may also occur. In rare cases potentially lethal myocarditis may occur. Other abnormalities such as right atrial enlargement or right ventricular hypertrophy are secondary due to PAH. Finally, patients with MCTD may have a higher risk for cardiovascular events, sometimes due to accelerated atherosclerosis—similar to patients with other chronic inflammatory diseases (eg, RA). Cardiovascular risk factors, including dyslipidaemia, low vitamin D levels and endothelial stiffness, may occur in patients with MCTD and require aggressive treatment to reduce the long-term risk for cardiovascular events (Bodolay et al, 2008; Hajas et al, 2010; Soltesz et al, 2010).

3.6.7 Renal manifestations of MCTD

Renal involvement is one of the most common complication in MCTD (Ortega-Hernandez and Shoenfeld, 2012), occurring in 11–40% of patients (Kobayashi et al, 1985; Kitridou et al, 1986). In contrast to SLE, severe

renal disease is very rare in MCTD, and the presence of anti-RNP antibodies may be protective against the development of an important renal manifestation with a diffuse proliferative glomerulonephritis (Lemmer et al, 1982). This is true for patients with MCTD and also for patients with SLE carrying anti-U1-RNP antibodies. Nevertheless, few cases of patients with MCTD and renal crisis, a potentially life-threatening complication with abrupt onset of severe hypertension and renal dysfunction, have been reported. In these patients, similar histopathological findings to those of scleroderma renal crisis have been reported (Satoh et al, 1994).

Other rare renal manifestations of MCTD are renal amyloidosis and renal infarcts in patients with anticardiolipin-positive MCTD. Finally, membranous nephropathy may occur. Usually, membranous nephropathy is mild in patients with MCTD, but might also be associated with significant proteinuria.

3.6.8 Neuropsychiatric manifestations of MCTD

Like renal disease, severe CNS manifestations are usually absent in MCTD, although there are a few case reports of CNS haemorrhage, myelitis, retinal vasculitis and progressive multifocal leucoencephalopathy in patients diagnosed with MCTD. Although severe manifestations are unusual, mild CNS involvement occurs in 25% of patients. As in patients with SSc, neuropathy of the trigeminal nerve is a common problem in MCTD. Headaches are an unspecific symptom. Vascular headaches are another frequent problem. Aseptic meningitis is a rare problem, but may be more common in MCTD than in the general population. Of note, anti-U1-RNP antibodies in the cerebrospinal fluid are associated with central neuropsychiatric manifestations, including aseptic meningitis, demyelinating syndromes, cognitive dysfunction, seizures and psychosis in patients with SLE and MCTD (Sato et al, 2010).

3.6.9 Haematological manifestations of MCTD

Anaemia and lymphopenia are commonly seen in patients with MCTD (Segond et al, 1978; Poullin et al, 1999). Low-grade anaemia, normally due to chronic disease, is observed in up to 75% of patients. In rare cases, patients present with Coombs positive haemolytic anaemia. Leukopenia and lymphopenia tend to correlate with disease activity. Autoimmune-mediated thrombocytopenia can become severe and manifest as thrombocytopenic purpura. Thrombocytopenia may be associated with the presence of antiphospholipid antibodies.

3.6.10 Laboratory abnormalities associated with MCTD

All patients diagnosed with MCTD have by definition high titres of ANAs with specificity against U1-RNP. Anti-IgG-U1-RNP autoantibodies against the 68 kDa protein of the U1-RNP complex of the spliceosome are particularly specific for MCTD. By immunofluorescence, anti-U1-RNP antibodies produce a speckled ANA pattern, very similar to that of anti-Sm and anti La/SSB autoantibodies.

The titres of U1-RNP autoantibodies tend to correlate with disease activity. A significant reduction of the anti-U1-RNP antibody titres was seen in patients in remission, whereas persistently raised titres were measured in patients with chronically active disease (Burdett et al, 1999).

Fifty per cent to 70% are also positive for RF. Antibodies directed to single-stranded DNA occur in 80% of patients, but anti-dsDNA-antibodies are rare. Antiphospholipid antibodies occur in about 15% of patients with MCTD compared with almost 40% of patients with SLE (Komatireddy et al, 1997). Unlike in SLE, most anticardiolipin antibodies in MCTD are β 2-glycoprotein independent (Mendonca et al, 1998). Antiphospholipid antibodies tend to correlate with thrombocytopenia, but not with thrombosis or abortion.

Other autoantibodies often detected in patients with MCTD are anti-hnRNP-A2, anti-fibrillin-1 and antinucleosome antibodies. A false-positive Venereal Disease Research Laboratory test is seen in about 10% of patients. Besides the presence of autoantibodies, hypergammaglobulinaemia is a common feature of MCTD. Furthermore, hypocomplementaemia or cryoglobulins might be found, but they seem not to be associated with renal disease or involvement of other organs in patients with MCTD (Smolen and Steiner, 1998*).

3.6.11 Clustering of clinical and laboratory features in MCTD

To identify specific subtypes of patients with MCTD, Szodoray and colleagues applied statistical cluster analysis to a group of 201 patients fulfilling the Alarcon-Segovia diagnostic criteria. The authors identified the three following clusters: (1) 77 patients with increased likelihood of having PAH, Raynaud's phenomenon and livedo reticularis; (2) 79 patients prone to interstitial lung disease, myositis and oesophageal hypomotility; and (3) 45 patients with a high rate of anti-CCP positivity and erosive arthritis. Survival was worst in cluster (1) with PAH being the major disease complication, resulting in the death of patients. Despite limitations in diagnosing certain disease manifestations (eg, PAH), this study may provide a preliminary system for further classification of the broad disease spectrum of MCTD (Szodoray et al, 2012).

3.7 MCTD and pregnancy

The data for the outcome of pregnancy in patients with MCTD are limited to a few retrospective studies and some case reports (Bennett and O'Connell, 1980; Kaufman and Kitridou, 1982; Siamopoulou-Mavridou et al, 1988; Lundberg et al, 1991a; Kitridou, 2005; Hoshino et al, 2008). Prospective, controlled studies of foetal and maternal morbidity and mortality in MCTD are lacking. Several conclusions can be drawn from the available studies. First, there is no evidence that the fertility of patients with MCTD is impaired. Second, patients might have a new onset of MCTD or the disease might flare up during pregnancy. Third, most reports suggest that foetal outcome is favourable in patients with MCTD, like that in healthy individuals. One study, however, showed a poor outcome and the rate of live births was reduced to 31% compared with 83% in controls. Finally,

neonatal lupus manifesting predominantly at the skin can occur in MCTD even in the absence of anti-Ro/SSA and anti-La/SSB antibodies. Nevertheless, neonatal lupus seems to be very rare in MCTD.

To sum up, the reports available suggest a modest risk of maternal flares during pregnancy. The foetal outcome remains controversial. Based on these findings and experiences in patients with SLE, the following guidelines have been proposed:

- The pregnancy should be planned for times of controlled disease activity.
- Patients should be followed up closely by an obstetrician and a rheumatologist
- Anti-U1-RNP, anti-Ro/SSA, anti-La/SSB, anticardiolipin antibodies and lupus anticoagulant should be determined at the onset of pregnancy, if not already known.
- Disease flares should be treated promptly with glucocorticoids.

3.8 Prognosis of MCTD

MCTD was initially described as a connective tissue disease with a good prognosis and an excellent response to glucocorticoids (Sharp et al, 1972*). Indeed, the prevalence of severe renal and CNS manifestations, which are a major cause of morbidity and mortality in SLE, is low (Lemmer et al, 1982; Burdt et al, 1999). Nevertheless, the incidence of PAH, which shortens life significantly, is high in MCTD (Burd et al, 1999). The excellent response to glucocorticoids was challenged by the results of subsequent follow-up studies (Nimelstein et al, 1980; Sullivan et al, 1984*). In general, the prognosis of MCTD is better than that of SLE and diffuse SSc (Burd et al, 1999). In many patients, the disease follows a benign course and goes into remission. Other patients show an aggressive disease course and may only have a partial response to immunosuppressive therapies.

Several studies, which included almost 200 patients at tertiary referral centres, showed a mortality rate of 16–28% after 10–12 years (Nimelstein et al, 1980; Burdt et al, 1999). Comparison with mortality data from age- and sex-matched controls is missing. Nevertheless, since MCTD mainly affects young women, the reported mortality rate may indicate an increased risk of premature death in patients with MCTD. PAH remains the leading cause of death in MCTD (Harmon and Leatherman, 1988; Burdt et al, 1999; Szodoray et al, 2012; Hajas et al, 2013), followed by infections. Other causes of death are rare and include myocarditis and renal crisis (Lash et al, 1986; Burdt et al, 1999). In children, deaths due to haemolytic uremic syndrome and glomerulonephritis have been reported. Death due to cardiovascular disease seems to be less common than in RA and SLE.

The morbidity in patients with MCTD can be high. Patients commonly have fatigue, arthralgias and arthritis, myalgias and myositis, serositis or gastrointestinal problems. In rare cases, patients may be disabled owing to deforming or mutilating arthritis. Secondary fibromyalgia with widespread musculoskeletal pain might also develop.

Treatment-induced increase of morbidity and mortality is another concern in patients with MCTD, and is mainly due to the prolonged use of glucocorticoids. The side effects of glucocorticoids include osteoporosis, aseptic bone necrosis, steroid myopathy, hypertension, steroid diabetes, acne, Cushing syndrome, gynecomastia and an increased risk of infections.

3.9 Treatment of MCTD

Unfortunately, no randomised controlled trials on the treatment of MCTD have been carried out. Thus, the management of patients with MCTD relies on interpolation of treatment guidelines for equivalent manifestations in SLE, SSc, RA and PM. In general, inflammatory manifestations such as arthritis, myositis, SLE-like skin disease and autoimmune-mediated anaemia and thrombocytopenia respond to immunosuppressive therapy. In contrast, other features such as Raynaud's phenomenon, acrosclerosis and most gastrointestinal manifestations are usually unresponsive to immunosuppression. Furthermore, treatment should be individualised for each patient, depending on the specific organs affected and the severity of the disease.

3.9.1 Treatment of the musculoskeletal manifestations of MCTD

All patients with MCTD with arthritis should have a radiographic evaluation of the hands and feet to screen for erosions. Arthralgias and mild non-erosive arthritis can be treated symptomatically with non-steroidal anti-inflammatory drugs (NSAIDs).

NSAIDs, however, might increase the risk of aseptic meningitis in MCTD. In more severe cases of arthritis, or if arthritis persists despite NSAID treatment, a trial of low-dose glucocorticoids and/or hydroxychloroquine should be started. For refractory cases or erosive arthritis, methotrexate is the first choice. If methotrexate fails to induce remission or if it is contraindicated, other DMARDs such as leflunomide may be used (Ortega-Hernandez and Shoenfeld, 2012).

Experience with biological agents targeting tumour necrosis factor α (TNF α) is limited. Two case reports of the use of TNF α antagonists for refractory, polyarticular arthritis in MCTD have been published. Both papers reported beneficial effects on the joint symptoms. Both patients, however, developed a SLE-like syndrome with fever, generalised arthralgias and myalgias, malaise and anaemia. In addition, anti-dsDNA antibodies became detectable and transient hypocomplementaemia developed, which resolved after discontinuation of the TNF α antagonists. Thus, TNF α antagonists cannot be recommended for treatment of arthritis in MCTD.

Myalgias in the absence of myositis can be treated with NSAIDs. Patients with diffuse musculoskeletal complaints should be evaluated carefully for the presence of reactive depression or fibromyalgia. In the absence of myositis, glucocorticoids should be avoided. Myositis in MCTD is often acute and can be accompanied by high-grade fever and in this case, it may respond to treatment with glucocorticoid in doses of 0.5–1.0 mg/kg/day prednisolone equivalent (Nimelstein et al, 1980; Burdt et al, 1999). Azathioprine,

methotrexate or intravenous immunoglobulins are further options for escalating treatment in severe cases with persistently raised muscle enzymes (Ortega-Hernandez and Shoenfeld, 2012).

3.9.2 Treatment of the vascular manifestations of MCTD

The management of Raynaud's phenomenon and PAH in patients with MCTD is dealt with in the online in-depth discussions. Briefly, conservative approaches, such as avoiding cold exposure, maintaining high core body temperature, gloves, smoking cessation and exogenous vasoconstrictors such as caffeine and sympathomimetic drugs, are the mainstay for treatment of Raynaud's disease (Sinnathurai and Schirber, 2013). Calcium channel blockers are the first line of medical treatment. Other medical approaches are topical glyceryl trinitrate and infusion of prostaglandins, which is particularly useful in patients with digital ulcers and gangrene. Smaller studies reported good effects of the angiotensin receptor blocker losartan and the selective serotonin reuptake inhibitor fluoxetine, which might be alternative choices for treatment of refractory cases. Randomised controlled trials show prophylactic effects of the endothelin receptor antagonist bosentan in patients with multiple digital ulcers. Bosentan, however, neither accelerated the healing of digital ulcers nor could it completely prevent their development (Korn et al, 2004; Matucci-Cerinic et al, 2011). Digital sympathectomy treatment should be reserved as the last resort for patients with critical ischaemia.

Almost all the presented data and recommendations on pharmacological and non-pharmacological treatment of Raynaud's phenomenon and digital ulcers derive from studies of patients with SSc or primary Raynaud's phenomenon. There are virtually no studies on patients with MCTD. One case report suggests that microvascular alterations in patients with MCTD might regress upon autologous haematopoietic stem cell transplantation (Aschwanden et al, 2008). The severely pathological scleroderma-like pattern at baseline improved to almost normal at most fingers of this patient after stem cell transplantation.

The treatment of PAH is complex and should be adjusted to the functional WHO class. Patients should be managed at specialised centres. General measures include diuretics (in patients with oedema), continuous oxygen supply (in patients with hypoxaemia), digoxin (in patients with supraventricular tachycardias associated with right ventricular dysfunction) and adapted regular cardiopulmonary exercise. Although evidence may be good for idiopathic PAH, data that support these general measures (therapeutic anticoagulation) in PAH associated with MCTD and other connective tissue diseases are limited.

Like Raynaud's phenomenon, the treatment suggestions for MCTD-associated PAH are mainly based on studies with idiopathic PAH or PAH associated with other connective tissue diseases, mainly SSc. PAH-specific drugs include prostacyclins, PDE5 inhibitors or endothelin receptor antagonists. In idiopathic PAH, patients who have a positive vasoreactivity testing during right heart catheterisation may respond well to calcium channel blockers. Recommendations for the use of calcium channel blockers in patients with CTD-associated PAH are changing. Since it is negative in most patients with CTD-associated PAH, vasoreactivity testing will be no longer

recommended in this group of patients. In parallel, calcium channel blockers will no longer be routinely used in CTD-associated PAH.

A report on 28 patients with connective tissue disease-associated PAH, including eight patients with MCTD, suggested that some patients might respond to immunosuppressive therapy with cyclophosphamide and glucocorticoids. Three out of eight patients with MCTD and PAH responded to the treatment and had a significantly improved 6 min walking distance and an improvement in haemodynamic function after 1 year of immunosuppressive therapy (Sanchez et al, 2006). A similar response rate was also seen in patients with SLE, whereas none of the patients with SSc responded.

The same group reported recently the outcome of 23 patients with MCTD- and SLE-associated PAH treated with immunosuppressant agents alone or in combination with pulmonary vasodilators for 6 months (Jais et al, 2008). All patients were in New York heart Association (NYHA) class II or III and most patients had not received disease-modifying antirheumatic drugs (DMARDs) before. Twelve patients responded to the treatment with cyclophosphamide and prednisolone with improvements in NYHA class, 6 min walking distance and mean pulmonary arterial pressure. Most responders had NYHA class II disease and a cardiac index >3.1 at baseline, suggesting that patients, particularly those with milder disease, might benefit from immunosuppressive therapy.

In another case, IL-6 blockade with tocilizumab improved functional activity and haemodynamic parameters in a patient with a severe and refractory form of MCTD-associated PAH (Furuya et al, 2010). The efficacy of immunomodulatory drugs for the treatment of MCTD- and SLE-associated PAH, however, needs to be confirmed in randomised controlled trials, before recommending them for routine treatment of connective tissue-associated PAH.

3.9.3 Treatment of the gastrointestinal manifestations of MCTD

Treatment of gastrointestinal symptoms of MCTD is often difficult and follows the same principles as the treatment of gastrointestinal involvement in SSc. Gastro-oesophageal reflux disease should be treated with proton pump inhibitors. In contrast to SSc, patients with MCTD with severe oesophageal dysfunction might benefit from glucocorticoid treatment (Marshall et al, 1990). A longitudinal study showed that patients with MCTD receiving oral glucocorticoids at an average dose of 25 mg/day had a significant increase of the lower oesophageal sphincter pressure and a trend to an improvement in oesophageal body peristaltic pressures. Secondary complications such as dysphagia due to strictures or mucosal rings should no longer occur with the consequent use of proton pump inhibitors but, if present, might require the use of endoscopic dilatation. Screening for Barrett's oesophagus might be indicated in patients with severe and longstanding gastro-oesophageal reflux disease.

Constipation is common in patients with MCTD. These patients should be advised to increase their fibre ingestion and fluid intake and to exercise. In more severe cases with pseudo-obstruction or intestinal pneumatosis, hospitalisation and bowel rest might be required. Case reports in patients with SSc report positive effects of octreotide, but the clinical experience is less encouraging.

3.9.4 Treatment of the pulmonary manifestations of MCTD

Pulmonary disease is common in MCTD, but is often asymptomatic and does not require specific treatment. Symptomatic pleuritis can often be managed with NSAIDs alone. In more severe cases, oral glucocorticoids should be added in a dose of 0.5–1.0 mg/kg/day. DMARDs are rarely indicated for pleural disease. Active alveolitis might warrant aggressive treatment: this includes oral glucocorticoids in doses of 1 mg/kg/day or intravenous pulses of high-dose steroids in severe cases as well as cyclophosphamide. The efficacy of oral cyclophosphamide for the treatment of active alveolitis and interstitial lung disease in patients with SSc has been analysed in a multicentre, placebo-controlled trial (Tashkin et al, 2006). After 12 months of treatment with a maximum dose of 2 mg/kg of body weight per day, a modest, but significantly higher forced vital capacity (2.53) was seen in the cyclophosphamide group than in the placebo group. This difference was maintained through the follow-up period of 1 year after treatment. In contrast, the TLCO did not differ significantly between the groups.

3.9.5 Treatment of the mucocutaneous manifestations of MCTD

Patients with SLE-like skin manifestations should be instructed to avoid sun exposure and to use sunscreen lotions. If these conservative approaches are not sufficient, patients might benefit from topical steroids or hydroxychloroquine. Systemic glucocorticoids or DMARDs should be avoided, but might be needed for severe, refractory cases.

3.9.6 Treatment of the cardiac manifestations of MCTD

Pericarditis in patients with MCTD is usually mild and can be treated with NSAIDs. In persistent cases, patients benefit from a short trial of glucocorticoids in doses of 0.5–1.0 mg/kg. In the rare cases of large effusions with cardiac tamponade, percutaneous or even surgical drainage might be necessary.

Myocarditis is a potentially life-threatening manifestation, which requires more aggressive treatment. Milder cases can be treated with oral glucocorticoids in a dose of 1 mg/kg/day. Severe cases often require intravenous pulses of glucocorticoids for the first 3 days followed by oral glucocorticoids. Since myocarditis tends to relapse, remission maintenance with azathioprine, mycophenolate mofetil or cyclophosphamide is often needed. Treatment for heart failure might be needed in severe cases. Digoxin should be avoided in patients with MCTD and myocarditis because it predisposes to ventricular arrhythmias.

3.9.7 Treatment of the renal manifestations of MCTD

Although severe renal manifestations are rare, some patients with MCTD might present with raised serum creatinine or high-grade proteinuria. These patients undergo renal biopsy to clarify the underlying pathology and guide treatment. Membranous glomerulonephritis is the most common manifestation. Milder forms with low-grade proteinuria can often be treated with ACE inhibitors alone. In the case of overt nephrotic syndrome, glucocorticoids are indicated, sometimes in combination with mycophenolate mofetil or cyclophosphamide. Supportive treatment with aggressive blood pressure control and lowering of cholesterol levels plays an important role in the long-term outcome of renal disease.

Renal crisis, which has been described in few cases, is managed according to the guidelines for SSc. High-dose ACE inhibitors with aggressive control of the blood pressure are the mainstay of treatment and should be started immediately upon suspicion. Angiotensin receptor antagonists might also be beneficial.

3.9.8 Treatment of the neural manifestations of MCTD

Although rare, neurological manifestations of MCTD can be severe. No randomised clinical trials in MCTD are available and all evidence is provided by SLE trials or case reports (Ortega-Hernandez and Shoenfeld, 2012). Vascular headache is a common problem in patients with MCTD. These can be treated with NSAIDs, low-dose tricyclic antidepressants or selective serotonin reuptake inhibitors. Triptans should be used with caution, because they can induce vasospasms and aggravate Raynaud's phenomenon. NSAIDs themselves might also be the cause of headaches in patients with MCTD. The prolonged use of high doses of NSAIDs might result in analgesia-induced headaches.

NSAIDs can also trigger aseptic meningitis, and in this case, all NSAIDs should be discontinued. Aseptic meningitis often responds promptly to a short course of glucocorticoids. The incidence of trigeminal neuropathy is also significantly increased in MCTD. Trigeminal neuropathy, the most common neurological symptom, is less responsive to glucocorticoids or immunosuppressive agents (Hagen et al, 1990). Patients with chronic pain may benefit from analgesics, antidepressants or anticonvulsant drugs.

3.9.9 Treatment of the haematological manifestations of MCTD

Mild anaemia or leukopenia tends to correlate with disease activity in MCTD and improves usually without specific treatment when the overall disease activity declines. Anaemic patients should be analysed for iron deficiency and, if present, treated appropriately. In cases of severe immune-mediated anaemia or thrombocytopenia, steroids at high doses of 1 mg/kg/day may be effective. In refractory cases, intravenous immunoglobulins, danazol, rituximab or splenectomy might be considered, and evidence from case studies for the use of rituximab is accumulating. These studies highlight a potential effect in correcting haematological disorders and other manifestations of patients with MCTD; they also demonstrate, however, that serious

adverse events (eg, serum sickness) might occur when treating patients with MCTD, and highlight the urgent need for controlled trials (Fearnley et al, 1978; Haroon et al, 2007; Rudolph et al, 2009).

SUMMARY POINTS

- Patients presenting with features of rheumatological diseases, who do not fulfil the criteria for a defined rheumatic disease, are diagnosed as having undifferentiated connective tissue disease (UCTD).
- In most patients with UCTD, no defined rheumatological disease will be diagnosed after several years of follow-up. For the remaining patients with UCTD, development of a defined rheumatological disease is more common than resolution of symptoms.
- Patients with overlap syndromes fulfil the criteria for two or more rheumatological diseases.
- Mixed connective tissue disease (MCTD) shares several features of systemic lupus erythematosus, systemic sclerosis, polymyositis and rheumatoid arthritis. Specific genetic, serological and clinical features, however, support the concept of MCTD as a separate clinical entity.
- Anti-U1-RNP antibodies directed against the U1-RNP complex of the spliceosome are the key biomarker for the diagnosis of MCTD.
- Four different classification criteria have been proposed for MCTD
- Characteristic, even not exclusive, clinical features of MCTD are Raynaud's phenomenon, puffy hands, the presence of severe arthritis, the high incidence of pulmonary arterial hypertension.
- Pulmonary arterial hypertension is the major cause of death in patients with MCTD.
- The prognosis of MCTD seems to be better than that of other defined connective tissue diseases such as systemic lupus erythematosus. The mortality of patients with MCTD, however, is significantly increased compared with age- and sex-matched controls.
- No clinical trials are available to guide the treatment of UCTD, overlap syndromes or MCTD. Treatment is based on experience with therapeutic approaches in other rheumatological diseases.

Connective tissue diseases: Concepts and pathogenesis, overlap syndromes, mixed CTD and undifferentiated CTD

Chiara Tani, Marta Mosca and Silvia Bellando-Randone

A previous version was co-authored by Gemma Lepri, Silvia Bellando Randone, Christian Beyer, Oliver Distler, Jorge H.W. Distler

IN-DEPTH DISCUSSION I

**Raynaud's syndrome and its treatment in patients with
UCTD and MCTD**

Raynaud's phenomenon (RP) is a well-defined clinical syndrome caused by a disorder of microvasculature and it is characterized by recurrent episodes of digital vasospasm triggered by exposure to physical/chemical or emotional stress. These episodes generally affect the fingers and toes, however also other extremities, as nose, ears and nipples may be involved [Prete M et al, 2014; Maverakis et al, 2014]. RP is often sub-classified in primary (with a relative benign course) and secondary, that is usually associated with an underlying disease, generally a connective tissue disease [Maverakis et al, 2014]. The majority of RP are primary forms that require only follow-up. In both cases, RP occurs after cold exposure or emotional stress. The onset of primary RP is often characterized by symmetric attacks involving both hands and patients do not present necrosis or tissue gangrene [LaRoy et al, 1992]. All patients should be assessed for the presence of associated symptoms/signs, to exclude the presence of an underlying connective tissue disease and to properly classify patient as having a primary or secondary form of RP. The most common symptoms/signs to investigate are: xerostomia, joint pain, photosensitivity, migraines, cutaneous sclerosis, telangiectasias, dysphagia, heartburn, and dyspnoea [LaRoy et al, 1992; Maverakis et al, 2014; Goundry et al, 2012]. Nailfold capillaroscopy and autoantibody profile play a central role in the assessment of patients with RP. Patients with primary RP have a normal capillaroscopy and a negative test for antinuclear antibodies [LaRoy et al, 1992].

In a recent study in RP patients, Trombetta C et al showed that capillary diameter on nailfold capillaroscopy is an independent predictor for development of SSc-associated RP while progression to secondary RP is unlikely when average capillary diameter is under 30 μm (Trombetta C, 2016).

Recently, Van Room AL et al. demonstrated that the degree of vasospasm and ischaemia provoked by stepwise cooling and recovery are positively associated with the severity capillaroscopic abnormalities in patients with primary and secondary RP (Van Room AL, 2016).

RP is a very common manifestation in UCTD and MCTD and can be associated with severe morbidity. Raynaud's syndrome occurs in about 50% of patients with UCTD and in more than 90 % of patients with MCTD. No clinical trials have specifically investigated the treatment of Raynaud's syndrome in patients with UCTD and MCTD. Therefore, the treatment principles for Raynaud's syndrome in UCTD and MCTD are based on guidelines from primary or secondary Raynaud's syndrome from other connective tissue diseases (e.g., SSc). The therapeutic options encompass supportive, alternative, pharmaceutical and surgical approaches.

Supportive therapies

Supportive therapies are the mainstay of the treatment of Raynaud's syndrome. Thus, patient education is extremely important. All patients should avoid cold exposure, which is not restricted to the extremities but includes the whole body [Gregory, 2013]. Patients should be encouraged to wear warm, isolating, or heatable gloves and shoes [Ko GD et al, 2002], but also cover their heads. Patients should stop cigarette smoking, in particular when they suffer from secondary Raynaud's syndrome and peripheral ischemia [Goodfield et al,

1990; Sinnathurai et al, 2013]. Avoiding emotional stress can also help to prevent Raynaud's attacks. Finally, patients with Raynaud's syndrome should avoid sympathomimetic drugs, which can stimulate vasoconstriction. If these conservative approaches are insufficient to reduce symptoms, more intensive therapies are needed.

Alternative therapies

Biofeedback and autogenic training might be beneficial in treating Raynaud's syndrome. Nevertheless, an evidence-based recommendation cannot be given for any of these approaches. A study on more than 300 patients did not demonstrate benefit of biofeedback on the frequency of Raynaud's attacks [Arch Intern Med. 2000; 160(8): 1101-8]. No clinical trials are available for autogenic training. Conflicting data exist regarding the efficacy of acupuncture. One study demonstrated a beneficial effect on primary Raynaud's phenomenon, which may be explained by increased release of sensory nerves and vasodilators such as substance P and calcitonin gene related peptide, whereas a small controlled study on patients with secondary Raynaud's syndrome did not demonstrate benefit [Appiah et al, 1997; Hahn et al, 2004; Gregory, 2013].

Drug therapies

Topical therapies

Topical therapies with isosorbide dinitrate and minoxidil did not improve symptoms in clinical studies. On the other hand, transdermal glyceryl trinitrate patches may reduce the number and the severity of RP [Sinnathurai et al, 2013]. However, side effects such as headaches are reported by up to 80% of patients. This side effect together with symptomatic hypotension reduce the usefulness of patches [The et al, 1995]. Topical glyceryl trinitrate improved peripheral blood flow and showed positive effects on the intensity and frequency of Raynaud's attacks in smaller studies [Anderson et al, 2002]. New formulations might be more effective and show less side effects (e.g., headaches, dizziness, skin irritation) [Chung et al, 2009]. Systemic nitrates should not be used because of the high incidence of side effects such as headaches.

Calcium channel blockers

Three different meta-analyses demonstrated a positive effect of calcium channel blockers for patients with primary and secondary Raynaud's syndrome [Thompson et al, 2005; Thompson et al, 2001, Ennis H, 2016]. This effect, however, was modest with a small reduction of frequency and severity of the attacks. The most recent Cochrane systematic review by Ennis H et al was focused on primary Raynaud's phenomenon; the randomised controlled trials included in this review provided moderate quality evidence that oral calcium channel blockers are minimally effective on frequency of the attacks and high-quality evidence that they have little effect on severity.

In addition, the individual response varied strongly between patients. Most evidence exists for nifedipine, which has been used in the large majority of studies. The efficiency of amlodipine and felodipine has also been demonstrated in single controlled trials [Kallenberg et al, 1991; La Civita et al, 1993; Schmidt et al, 1989]. In contrast, conflicting data exist for other calcium channel blockers such as diltiazem. It seems to produce a decrease in the severity and frequency of primary Raynaud's phenomenon but not in the secondary one. Unwanted side effects such as hypotension, dizziness, headache, peripheral oedema, and flush occur quite frequently. In addition, the reduction of the lower oesophageal sphincter tone might increase the incidence of gastro-oesophageal reflux disease. Thus, treatment should start with a low dose (e.g. nifedipine retard 10 mg) and increase further as tolerated by the patient.

Prostaglandin analogues: Iloprost

The synthetic prostacyclins analogue iloprost does not only induce vasodilatation, but also inhibits platelet aggregation and modulates the expression of adhesion molecules on endothelial cells. Intravenous iloprost significantly reduces the frequency of attacks and improves the healing of fingertip ulcers in SSc patients on the evidence level of a meta-analysis, while oral iloprost has no consistent effects [Pope et al, 2000]

The application schemes for i.v.-iloprost vary considerably between different studies. Doses between 0.5 – 2.0 ng/kg/min for 6 to 8 hours are commonly used. Application periods of 10 days every three month have been suggested to be particularly beneficial [Milio et al, 2006]. The published experience with iloprost in patients with primary Raynaud's syndrome or other connective tissue disease is limited. Common side effects include hypotension, headache, gastrointestinal problems and an increased bleeding risk in patients receiving platelet aggregation inhibitors or oral anticoagulants. Beneficial effects were also observed in smaller studies for alprostadil and misoprostol.

Angiotensin-II receptor type 1 antagonists (AT-1 antagonists)

A study on patients with primary and secondary Raynaud's phenomenon demonstrated that the AT-1 antagonist losartan has beneficial effects similar to that of nifedipine [Dziadzio et al, 1999]. The reduction of the frequencies of attacks was even better than for nifedipine. However, no significant differences were found between the two groups in laser Doppler-flow examination following cold challenge. The major side effect was dizziness. In general, the frequency of side effects was lower than with nifedipine.

Selective serotonin re-uptake inhibitors (SSRI)

The serotonin reuptake inhibitor fluoxetine at a dose of 20 mg/d was more effective in one study than nifedipine [Coleiro et al, 2001]. In this study, no statistically significant effect was observed for nifedipine. Side effects of fluoxetine were apathy and concentration deficits. The rate of side effects was lower than with nifedipine [Gregory, 2013]

Phosphodiesterase inhibitors

Phosphodiesterase inhibitors interfere with the degradation of the vasodilative mediator cGMP. The phosphodiesterase 5 inhibitor sildenafil significantly reduced the frequency and duration of attacks at a dose of 50 mg twice daily in patients with secondary Raynaud's syndrome [Fries et al, 2005]. Vardenafil, another phosphodiesterase 5 inhibitor, had similar effects in an uncontrolled study [Caglayan et al, 2006]. Evidence for the long-acting PDE V-inhibitor tadalafil is conflicting; Tadalafil did not show efficacy in a randomized placebo-controlled trial with 39 SSc patients suffering from Raynaud's syndrome [Schiopu et al, 2009] by contrast, tadalafil as add-on therapy improved symptoms of Raynaud's syndrome, healed and prevented new digital ulcers, and improved quality of life in another double-blind randomized cross-over trial with SSc and MCTD patients [Shenoy et al, 2010]

In 2014, Lee EY et al published the results of a double-blind, randomized, cross-over study comparing the efficacy on secondary Raynaud's phenomenon of a new phosphodiesterase type 5 inhibitor udenafil with amlodipine. Amlodipine and udenafil similarly decreased the rate of the attacks significantly. In addition, udenafil was more effective in improving the blood flow in digital arteries compared with amlodipine (Lee EY, 2014)

The endothelin receptor antagonist

The non-selective endothelin receptor antagonist bosentan, also used in treatment of pulmonary arterial hypertension, has an emerging role in the treatment of Raynaud's phenomenon and digital ulcers. In SSc case reports, patients treated with this drug for PAH reported to have an improvement of Raynaud's phenomenon and digital ulcers [Sinnathurai et al, 2013; Arefievk et al, 2011]. Bosentan prevents the development of fingertip ulcers in patients with SSc as shown in two randomized, controlled trials (RAPIDs-1 and 2). Bosentan, however, did not improve the healing process of digital ulcers. It was effective in reducing the relapse of multiple (≥ 3 DUs) – but not single- ulcers [Korn et al, 2004; Matucci-Cerinic et al, 2011]. There are no proven effects on primary or secondary Raynaud's phenomenon.

Recently, Bellando-Randone S et al reported in a small cohort of patients with Raynaud's phenomenon secondary to SSc a significant improvement of the Raynaud Condition Score and nailfold capillaroscopy pattern after 6 months of combination therapy with bosentan and sildenafil (Bellando-Randone S, 2016)

Other drug treatments

The alpha receptor blocker prazosin had modest efficiency in two controlled studies, but its clinical use is limited due to sometimes severe and frequent orthostatic hypotension [Pope et al, 2000]. The data for ACE inhibitors are inconsistent. The selective serotonin receptor antagonist ketanserin reduced only mildly the duration of attacks, but demonstrated otherwise no significant benefits.

Since statins can slow down the progression of vascular injury in cardiovascular disease, their effects on SSc-related Raynaud's phenomenon and DUs have been addressed by two recent randomized controlled trials; while atorvastatin at a dose of 40 mg/d for four months improved Raynaud's phenomenon and reduced the number DUs in an Egyptian study [Abou-Raya et al, 2008], a European study did not find any significant differences between atorvastatin at a dose of 20 mg/d for two months and placebo [Sadik et al, 2010]. Apart from treatment dose and duration, disease duration and severity of vascular injury might account for these different results. Given the good tolerability and the relatively low costs for statins, however, future studies should identify patients with CTD-associated Raynaud's phenomenon and DUs who might benefit from a statin therapy.

Medications to improve rheological properties have also been tested in patients with Raynaud's syndrome. No effect has been observed for low-dose acetylsalicylic acid. Mild effects have been suggested by single studies for low-molecular heparin and ginkgo-biloba preparations. Two studies analysed the effects of pentoxifylline in patients with primary Raynaud's syndrome. Pentoxifylline did not reduce the frequency and duration of the attacks in one study, but was suggested to improve peripheral hemodynamic in a small controlled trial.

Surgical therapies

Surgical approaches are proximal cervical and localized digital sympathectomy. A persisting beneficial effect was observed in only a minority of patients in a retrospective study for proximal cervical sympathectomy. A smaller study demonstrated an improved microvascular perfusion in 22 SSc patients treated with localized digital sympathectomy. The long-term outcome of this therapy, however, remains unknown [De Trafford et al, 1988; Ruch et al, 2002]. More recently, digital periarterial sympathectomy demonstrated to be a simple and relatively nonaggressive technique without adverse side effects and with excellent medium-term results in a large series of patients with post-traumatic Raynaud syndrome (Letamendia A, 2016).

Thus, surgical approaches should be restricted to treatment-resistant, acute critical ischemia and should be performed at experienced centres.

Other therapies

Botulinum toxin A has been proposed for the treatment of Raynaud's phenomenon because of their ability to modulate sympathetic nerve conduction and thus reduce vasoconstriction; however, a recent systematic review concluded that despite many promising reports, there is insufficient evidence to assess the efficacy of botulinum toxin A in Raynaud's phenomenon and further research is warranted before recommending this therapy in clinical practice.

Summary

There are no evidence-based therapies for Raynaud's syndrome in patients with UCTD or MCTD due to the lack of specific studies with these patient populations. Considering the evidence for primary and secondary Raynaud's phenomenon (the latter one in patients with SSc), the following conclusions can be drawn: Two of the mentioned therapeutic approaches, nifedipine and intravenous iloprost, can be recommended with evidence grade I a (evidence based on the meta-analysis of randomized controlled studies). The evidence for intravenous iloprost is mainly based on studies with secondary Raynaud's syndrome. Grade I b evidence (evidence based on at least one randomized controlled study) exists for amlodipine, felodipine, losartan, fluoxetine and sildenafil. For all other approaches, the evidence is lower, because (i) randomized, controlled trials demonstrated conflicting results, (ii) positive effects have only base on case reports or uncontrolled studies or (iii) the effects were small and only involved certain aspects (e.g. the frequency of attacks, but not hemodynamic and intensity of attacks).

IN-DEPTH DISCUSSION II

Diagnosis of pulmonary arterial hypertension

Pulmonary arterial hypertension (PAH) occurs as a severe manifestation of several connective tissue diseases such as systemic sclerosis (SSc) mixed connective tissue disease (MCTD), systemic lupus erythematosus (SLE), overlap syndromes and undifferentiated connective tissue diseases [Shahane, 2013].

In the most recent literature, the highest rates of PAH are reported in MCTD (2–24%) followed by systemic lupus erythematosus (SLE) (up to 17.5%), and systemic sclerosis (SSc) (nearly 10%) [Gunnarsson et al, 2013; Wigley FM et al, 2005; Pèrrez-Penate GM et al, 2016; Avouac J et al, 2010]. PAH is more rarely observed in inflammatory myopathies and Sjögren syndrome.

Estimates of its prevalence among different cohorts are variable; this wide prevalence is explained by the patient's selection criteria, the lack of a standard definition for PAH, and the different PH diagnostic approaches [Doppler echocardiography or right heart catheterization]. Echocardiography, indeed, tends to overestimate pulmonary artery pressures and can have a high rate of false-positive results. Thus, the real prevalence might be somewhat lower than reported in some studies using estimated right ventricular systolic pressure on echocardiography as the only diagnostic method.

Moreover, challenges of PAH management include clinically undetected CTDs at the time of PAH clinical presentation and diagnosis; this is a crucial point as CTD-associated PAH has a poorer prognosis and worse cardiac dysfunction compared with idiopathic PAH. In a recent study, Cavagna L et al showed a high prevalence (17/49 pts) of undiagnosed CTDs in patients with iPAH without a previous rheumatological assessment (Cavagna L, 2016).

Regardless of the challenges in determining its prevalence, PAH is a major cause of morbidity and mortality in connective tissue diseases. Three-year survival rates in idiopathic PAH are as low as 48% after diagnosis – even after exclusion of risk factors and associated diseases. Survival is worse for those with respiratory disease-associated SSc-PAH (3-year survival, 28%), whereas survival among patients with exercise-induced SSc-PAH is superior (3-yr survival, 86%) [Condiffe et al, 2009].

PAH is the most serious complication and the major cause of death in patients with MCTD [Shahane, 2013. Tani et al, 2014]. A recent study showed that in patients with CTD-PH, the 3-year survival rate was 87% [Kang et al, 2015]. In the longitudinal study of patients with MCTD mentioned above, 9/11 deaths were due to PAH. These poor outcomes highlight the need for careful follow-up and early diagnosis because therapies are available to treat patients with PAH associated with connective tissue diseases. In addition to therapies for idiopathic PAH and PAH associated with SSc, PAH associated with MCTD might respond to immunosuppressive therapy with intravenous cyclophosphamide and systemic glucocorticosteroids, which appears to prolong survival in these patients [Legendre et al, 2014].

Clinical symptoms

Clinical symptoms of PAH are diverse and unspecific. The cardinal sign is dyspnoea on exertion, but many patients do not mention these symptoms during past medical history. Therefore, it is important to ask specific, individual questions (e.g. “Are you short of breath when climbing the stairs to your flat” instead of “Do you experience shortness of breath on exertion”). Other symptoms that should alert the clinical suspicion of PAH include fatigue, weakness, angina, and syncope/pre-syncope and pleuritic chest pain [Ortega-Hernandez et al, 2012. Hajas et al, 2013]. Physical signs such as left parasternal lift, accentuated pulmonary component of S2, pan systolic murmur of tricuspid regurgitation, diastolic murmur of pulmonary insufficiency and right ventricular S3 are indicative but require considerable experience to be detected [Galié et al, 2004]. Other findings on physical examination include jugular vein distension, hepatomegaly, peripheral oedema, and ascites. Notably, these symptoms are late manifestations of the disease. Hemodynamic as well as morphological changes in the pulmonary vasculature occur long before these clinical findings are detectable [Distler et al, 2006].

Diagnostic screening tests

Unspecific and late clinical signs and symptoms raise a need for diagnostic screening tools in patients at risk of PAH. The best characterized and most often used screening test is transthoracic Doppler-echocardiography (TTE). Regular TTE screening, as recommended for patients with SSc, might also be useful in patients with MCTD because of the high prevalence of PAH [Galié et al, 2009]. For patients with SSc, regular TTE screening protocols can both detect PAH in milder stages and improve survival of SSc-PAH patients [Humbert et al, 2011].

TTE is a non-invasive, readily available and feasible diagnostic test. Nevertheless, there are limitations: first, TTE is strongly dependent on the experience of the examiner. Second, TTE is imprecise in patients with borderline or mild pulmonary hypertension, both under- as well as overestimating the right ventricular systolic pressure (RSVP, equivalent to the pulmonary artery systolic pressure in the absence of pulmonary outflow obstruction). This can lead to both false negative and positive results in the screening process [McQuillan et al, 2001].

According to the 2015 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension [Galiè N, 2016] the echocardiographic probability of pulmonary hypertension in symptomatic patients is strictly related to the tricuspid regurgitation velocity measurement and other echocardiographic signs (see tables 1 and 2)

Table 1: Echocardiographic probability of pulmonary hypertension in symptomatic patients with a suspicion of pulmonary hypertension (adapted from Galiè N et al, 2016)

Peak tricuspid regurgitation velocity (m/s)	Presence of other echo 'PH signs' ^a	Echocardiographic probability of pulmonary hypertension
≤2.8 or not measurable	No	Low
≤2.8 or not measurable	Yes	Intermediate
2.9–3.4	No	
2.9–3.4	Yes	High
>3.4	Not required	

Table 2: Echocardiographic signs suggesting pulmonary hypertension used to assess the probability of pulmonary hypertension in addition to tricuspid regurgitation velocity measurement (adapted from Galiè N et al, 2016)

A: The ventricles ^a	B: Pulmonary artery ^a	C: Inferior vena cava and right atrium ^a
Right ventricle/left ventricle basal diameter ratio >1.0	Right ventricular outflow Doppler acceleration time <105 msec and/or midsystolic notching	Inferior cava diameter >21 mm with decreased inspiratory collapse (<50 % with a sniff or <20 % with quiet inspiration)
Flattening of the interventricular septum (left ventricular eccentricity index >1.1 in systole and/or diastole)	Early diastolic pulmonary regurgitation velocity >2.2 m/sec	Right atrial area (end-systole) >18 cm ²
	PA diameter >25 mm.	

a: Echocardiographic signs from at least two different categories (A/B/C) from the list should be present to alter the level of echocardiographic probability of pulmonary hypertension.

Additional tests such as 6-minutes-walk-test and circulating brain natriuretic peptide (BNP) levels might increase the specificity of PAH screening in patients with MCTD and other connective tissue diseases [Ortega-Hernandez et al, 2012; Distler et al, 2006]. A significant decrease in DLCO without concomitant changes of restrictive parameters is the strongest risk factor for the later development of PAH in patients with SSc [Steen et al, 2003]. Whether the same holds true for patients with MCTD, however, is unknown. The 6-minute walk

distance is established and, at least in part, validated to assess the severity in patients with PAH. It is also used for follow-up to assess treatment response. [Avouac et al, 2010]. However, in what extent the musculoskeletal manifestations of connective tissue diseases can interfere with the validity of this outcome measure has still to be established. Recently, 6MW stress echocardiography has been evaluated in a prospective 5-years cohort of patients with CTD-associated PAH; the authors demonstrated that this test can provide an incremental prognostic value of PH development in CTD. (Kusunose K et al, 2015)

Finally, rising, rather than elevated, NT-pro BNP levels may indicate increased right ventricular load in early stages of PAH but are not specific for pulmonary hypertension.

New recommendations for screening and detection of CTDs associated PAH, concerning in particular SSc and CTDs with scleroderma features, have been published by Khanna et al. According to these recommendations, patients should be evaluated with PFT (including DLCO), transthoracic echocardiography and NT-proBNP initially and at least once annually thereafter. If patients complain new signs or symptoms, the complete screening needs to be repeated [Khanna et al, 2013]. The DETECT algorithm, generated to guide RHC in SSc patients with increased risk of PAH, has not been validated in MCTD. See Table 3 for Recommendations for screening and early detection of CTD-PAH [Khanna et al, 2013].

Right heart catheterization

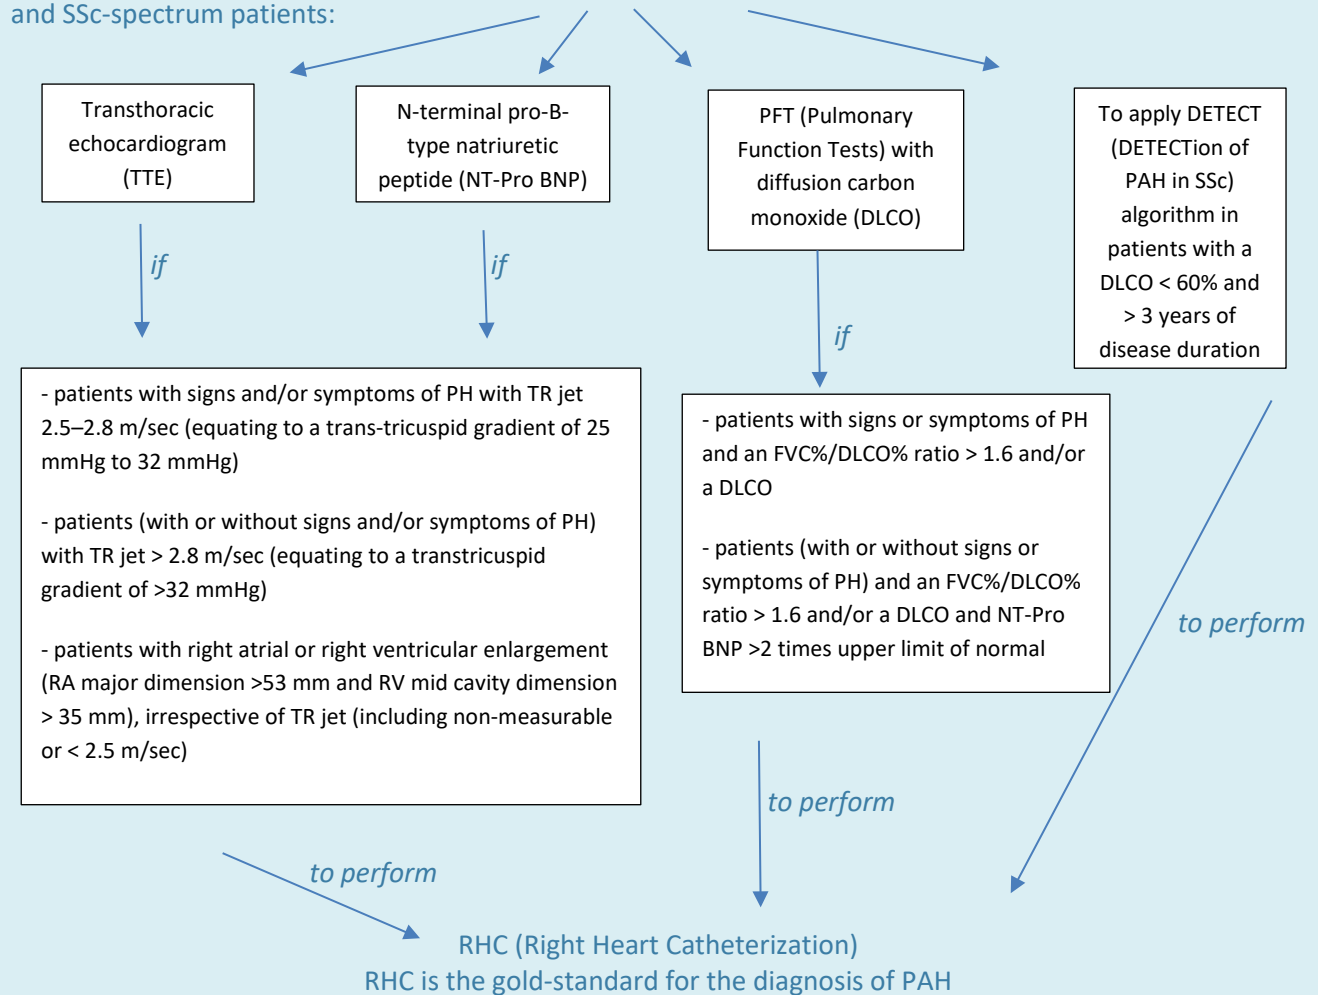

Once the diagnostic screening tests suggest PAH, the diagnosis must be confirmed by direct measurement of the pulmonary haemodynamics by right heart catheterization. Right heart catheterization is the gold-standard for the diagnosis of PAH. The hemodynamic parameters that characterize PAH include a pulmonary arterial pressure ≥ 25 mmHg and a normal pulmonary capillary wedge pressure of ≤ 15 mmHg on right heart catheterization [Simmonneau et al, 2009].

Vasoreactivity, as shown by a decrease of the pulmonary arterial pressure upon challenge with inhaled NO in patients with PAH during right heart catheterization, is rare in patients with connective tissue diseases, including MCTD. Thus, upcoming guidelines may no longer recommend vasoreactivity testing in patients with CTD-associated PAH in routine clinical practice. Finally, it is important to exclude other causes of pulmonary hypertension, such as interstitial lung disease (e.g., by high resolution CT) and chronic thromboembolic disease (e.g. by ventilation and perfusion lung scan). Chronic thromboembolic disease might be particularly relevant for patients with MCTD considering the increased prevalence of anti-phospholipid-antibodies. On the other hand, the presence of anti-phospholipid-antibodies does not appear to correlate with thrombotic events in patients with MCTD [Komatireddy et al, 1997; Hoeper et al, 2013].

Table 3 Recommendations for screening and early detection of CTD-PAH, adapted from Khanna et al, 2013.

Patients with MCTD or other CTD with scleroderma features should be evaluated and screened for PAH similar to patients with SSc.

Blood and instrumental examinations to perform annually or at the onset of any new signs/symptoms in SSc and SSc-spectrum patients:

Systemic lupus erythematosus: pathogenesis and clinical features

Marília Rodrigues, Luís Sousa Inês and Caroline Gordon

Previous versions were coauthored by Sofia Tosounidou, George Bertsias, Caroline Gordon, Dimitros T. Boumpas, Ricard Cervera, Gerard Espinosa, David D'Cruz

LEARNING OBJECTIVES

- ➔ Use epidemiology and evidence about the disease course to support clinical decisions
- ➔ Understand the key events in the pathogenesis of systemic lupus erythematosus (SLE)
- ➔ Describe and explain the clinical manifestations of SLE in the mucocutaneous, musculoskeletal, renal, respiratory, nervous, cardiovascular, pulmonary, haematological, gastrointestinal and eye domains
- ➔ Make a diagnosis of SLE based on history, physical examination, and interpretation of serological and laboratorial results
- ➔ Critically evaluate the classification criteria, their uses and limitations
- ➔ Assess patients according to the activity and damage indices as part of a decision-making process
- ➔ Recognize the specificities in the assessment of different clusters of patients (children, childbearing women, elderly)
- ➔ Monitor aspects related to the chronicity of SLE as damage, comorbidities and their impact on patient quality of life

1 Introduction

1.1 Definition

Systemic lupus erythematosus (SLE) is the prototypic multisystem autoimmune disease with a broad spectrum of clinical presentations encompassing almost all organs and a chronic course, which can vary from mild to life-threatening.

1.2 Major milestones in the history of lupus

The term 'lupus' was first used during the Middle-Ages to describe erosive skin lesions evocative of a 'wolf's bite'. In 1846 the Viennese physician Ferdinand von Hebra (1816–1880) introduced the butterfly metaphor to introduce the malar rash. He also used the term 'lupus erythematosus' and published the first illustrations in his Atlas of Skin Diseases in 1856. Lupus was first recognised by Moriz Kaposi (1837–1902) as a systemic disease with visceral manifestations. The systemic form was further established by Osler in Baltimore and by Jadassohn in Vienna.

2 Epidemiology

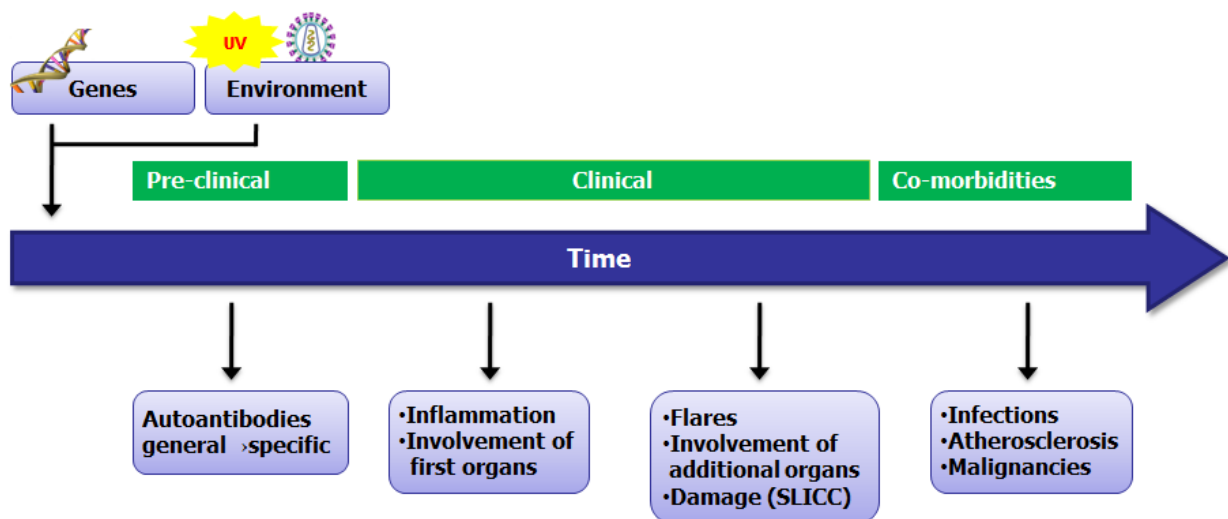

Estimated incidence rates of SLE in North America, South America and Europe range from 1 to 23 per 100 000 per year (Pons-Estel et al, 2010; Somers et al, 2014). Prevalence in adults is as high as 150 per 100 000 people in the USA. Age, gender, geographical differences and ethnicity are risk factors for SLE and influences clinical presentation and patient outcomes (Duarte et al, 2011*; Lewis et al, 2016). In Europe, prevalence ranges from 20 to 97 per 100 000 (Alonso et al, 2011; Bertsias et al, 2013; Arnaud et al, 2014 ; Rees et al, 2016a). Women are affected up to twelve times more frequently than men; African-American and Hispanics are affected much more often than Caucasians, and have higher disease morbidity (Rivest et al, 2000; González et al, 2014; Ugarte-Gil et al, 2016). In USA, the average incidence and prevalence rates of childhood SLE is 2.2 and 9.7 cases per 100 000 per year, respectively, with nearly 40% having renal involvement (Hiraki et al, 2012). Disease onset is between the ages of 16 and 55 in 65% of patients, 20% present before age of 16 and 15% after the age of 55. Men with lupus tend to have less photosensitivity, more serositis and nephritis, an older age at diagnosis and a higher mortality rate than women (Gonçalves et al, 2015; Riveros Frutos 2016). SLE tends to be milder in the elderly with lower frequency of renal and central nervous system (CNS) involvement (Mina and Brunner, 2013).

2.1 Natural history and disease course

SLE is a chronic disease and has a waxing and waning course with significant morbidity (figure 1). The disease starts with a preclinical phase characterised by nonspecific autoimmune abnormalities and proceeds to a more disease-specific autoimmunity phase (Bertsias et al, 2010b). Likewise, the clinically overt disease may start with single manifestations that are nonspecific, such as Raynaud's phenomenon, arthritis or autoimmune

thrombocytopenia. It may take years for patients to develop enough clinical and immunological disturbances leading to SLE diagnosis, although some patients present from inception with a full-blown disease. For these reasons, time of disease onset is often uncertain and diagnosis may be delayed. Flares of disease activity are mostly unpredictable in time and can include a varying combination of old and new manifestations early in the disease course. With time, clinical presentation may result not only from lupus flares, but also from damage accrual related to disease, treatment (namely glucocorticoids and immunosuppressives) and comorbidities, such as infections, chronic kidney disease, osteonecrosis, osteoporotic fractures, cataracts, Jaccoud's arthropathy, atherosclerosis, and malignancy. Current survival rates of SLE patients at 10 years after diagnosis in Europe are 90% or higher, but life expectancy is still lower than in the general population (Rees et al, 2016b). Predictors of mortality include high disease activity, damage accrual and low socioeconomic status. Infections, cardiovascular disease, malignancy and disease activity are major causes of death (Cervera et al, 2003; Doria et al, 2006; Duarte et al, 2011*; Lopez et al, 2012; Bruce et al, 2015*).

2.2 Aetiology

The aetiology of SLE includes genetic, hormonal and environmental components. These factors lead to an irreversible breakdown of immunological tolerance manifested by aberrant immune responses against endogenous nuclear and other self-antigens (Tsokos et al, 2011).

2.2.1 Genetic factors

Siblings of patients with SLE are 30 times more likely to develop SLE than people without an affected sibling. Large genome-wide association studies have confirmed the importance of genes associated with immune response and inflammation, DNA repair, adherence of inflammatory cells to the endothelium and tissue

response to injury (Guerra and Vyse, 2012; Bentham et al, 2015). They also highlight the importance of transcription factors acting as upstream regulators, Toll-like receptors and type 1 interferon (IFN) signalling pathways. Some of the genetic loci may explain the susceptibility to disease and also its severity (Taylor et al, 2008; Rullo and Tsao, 2013). The genetic risk for SLE may be influenced by epigenetic effects, such as DNA methylation and post-translational histone modifications, which can be either genetically determined or environmentally induced (Patel and Richardson, 2013). The most well understood type of epigenetic factor is DNA methylation, which plays a role in a variety of human processes. Differences in the methylation status of genes may explain, at least in part, the discordance for SLE in 3 out of 4 pairs of identical twins (Javierre et al, 2010).

2.2.2 Environmental factors

Candidate triggers of SLE include ultraviolet light, drugs, smoking, cosmetic products, occupational exposures and infectious or endogenous viruses or viral-like elements (Cooper et al, 2010; Duarte et al, 2011*; Zandman-Goddard et al, 2012). Sunlight and ultraviolet radiation exposure, namely to UV-B, is a widely recognized risk factor for SLE onset. Certain drugs can induce autoantibodies, some of whom develop signs of autoantibody-associated disease (Bukhari 2012). Over 100 drugs have been reported to cause drug-induced lupus, the most common being tetracyclines. A genetic predisposition may play a role, particularly in the case of agents that are metabolised by acetylation such as procainamide and hydralazine, with the disease being more likely to develop in slow acetylators (Reidenberg et al, 1993). Anti-TNF-alpha drugs were also reported to induce lupus, usually self-limiting after stopping therapy (Williams et al, 2009). From potential viral triggers, there is better evidence for an association with Epstein-Barr virus infection (Parks et al, 2005). Current smoking was associated in a meta-analysis with an increased risk of SLE (Costenbader et al, 2004). There is evidence for an increased risk with silica exposure. Available studies found no association with alcohol, hair dyes, or silicone-containing implants.

2.2.3 Hormonal factors

The marked predominance of women with SLE, its highest incidence and prevalence found in women of childbearing age, and the equal prevalence in men compared to women before puberty and after menopause suggests an important role of endogenous oestrogens and androgens in SLE aetiology (Duarte et al, 2011*). In murine models, experimental data support a role of oestrogens in lupus development, while androgens delay lupus onset and are associated with a milder disease. There is conflicting data from observational studies on a potential effect of oral contraceptives and hormonal replacement therapy in risk of developing SLE. No association was found between pregnancies and risk of developing SLE in two case-control studies (Bengtsson et al, 2002; Cooper et al, 2002).

3 Pathogenesis

3.1 Key systemic events

The pathogenesis of SLE involves the interplay of susceptibility genes, environmental risk factors, immune cells and molecules that participate in apoptosis, innate and adaptive immune responses (Tsokos et al, 2016*). In genetically predisposed individuals, environmental factors act as triggers of loss of tolerance to self-antigens, eliciting autoimmunity. Downstream elements that drive a self-sustained loss of tolerance, spreading and maintenance of autoimmunity are still poorly understood. Pathogenic processes are heterogeneous across different disease features, patients, populations and ethnic groups. An overview of key events in immunopathogenesis of SLE is presented in figure 2.

Over 40 genetic loci identified through genome-wide association studies (GWAS) are confirmed to be associated with SLE (Cui et al, 2013). Many of these genetic factors also confer susceptibility to other autoimmune diseases. Susceptibility to SLE conferred by each gene is limited, generally with a relative risk less than 2. A number of rare monogenic disorders are also implicated in SLE and lupus-like disease (Belot et al, 2012). The susceptibility genes are connected with three major immune pathways: (1) apoptotic waste clearance; (2) nucleic acid innate sensing by Toll-like receptors (TLR) and downstream interferon (IFN) signalling pathways; (3) lymphocyte signalling within T or B cells. Epigenetic mechanisms are potentially implicated in SLE susceptibility and disease activity: these include processes such as DNA methylation, post-translational histone modifications, and noncoding RNAs that can durably modify gene expression. DNA hypomethylation typically causes overexpression of genes and was found globally increased in T cells from patients with active SLE and specifically in IFN-stimulated genes (Tsokos et al, 2016*).

A key concept in the pathogenesis of SLE is an imbalance between production of apoptotic waste and its disposal: when the burden of apoptotic cells exceeds clearance rate, the accumulated apoptotic debris can illicit abnormal immune responses (Casciola-Rosen et al, 1994). Increased apoptotic cell load can be generated by exposure to ultraviolet light, infections and other environmental risk factors for SLE. Abnormal apoptotic pathways contribute to failure of the mechanisms that usually prevent immune activation in response to endogenous cellular debris. Neutrophils are key inflammatory participants that extrude nuclear material, forming neutrophil extracellular traps (NETs), a source of yet more nucleic acid antigens in SLE (Dieker et al, 2016). Nucleic acids (DNA, RNA) contained in apoptotic debris can stimulate an inflammatory response through activation of nucleic-acid recognition receptors, such as Toll-like receptors (TLR), which are constituents of the innate immune system (Tsokos et al, 2016*). The TLRs are expressed in immune cells, including dendritic cells (DC), B and T cells, and macrophages, as well as nonimmune cells (epithelial cells, fibroblasts). TLRs reside in the endoplasmic reticulum, with TLR3, TLR7 and TLR8 recognizing RNA, while TLR9 senses DNA. Experimental data support more strongly a role for TLR7 and TLR9 in SLE susceptibility, with more

limited evidence implicating TLR3 and TLR8 (Wu et al, 2015). Current models of SLE pathogenesis postulate a central role for TLRs in which they engage self-nucleic acids, drive loss of tolerance and induce a strong type I interferon (IFN) production (Tsokos et al, 2016*).

The plasmacytoid DCs (pDC) are immune cells that produce the highest levels of type I IFN after activation by TLRs. Hydroxychloroquine, a cornerstone of SLE treatment reduces TLR7/9 activation and Type I IFN production by pDC (Sacre et al, 2012). Type I IFN and other cytokines promote B-cell differentiation and loss of tolerance. B-cell activating factor (BAFF or BLyS) is upregulated by type I IFN and is an important driver of B-cell activation, survival and autoantibody production in SLE (Liu et al, 2011). BAFF is the target of belimumab, a drug approved for SLE treatment. Once activated, B cells mature, expand and secrete antibodies, which enhance the adaptive immune response. Type I IFN also induces differentiation of conventional myeloid DC (mDC) and auto-antigen presentation by mDCs to CD4-positive T cells in SLE (Blanco et al, 2001). Thus, both pDCs and mDC are thought to be pivotal to the disease process in SLE (Tsokos et al, 2016*).

T-cell and B-cell abnormalities are considered central to SLE pathogenesis and include: loss of T-cell tolerance; aberrant T-cell to B-cell interactions leading to stimulation of autoreactive B cells; differentiation and expansion of pro-inflammatory interleukin-17 (IL-17) producing T-cells; defective or deficient regulatory T-cells (T_{reg}), that represent an important checkpoint against autoreactive lymphocytes; aberrant development of B-cells, leading to a break in B-cell tolerance and increased survival of autoreactive clones (Dörner et al, 2016; Tsokos et al, 2016*). B-cells contribute to SLE through their response to autoantigens, with production of the autoantibodies that constitute a hallmark of the disease, as well as by autoantibody- independent mechanisms. Autoantibodies bind to self-antigens, forming immune complexes that activate complement, and through binding Fc receptors, drive inflammation at target tissues, such as the skin and kidney. Other roles of B-cells in SLE include their ability to present autoantigenic peptides to T cells, drive innate responses mediated by the expression of TLRs, and production of an array of proinflammatory and regulatory cytokines (Dörner et al, 2016). Co-stimulatory cell receptors and ligands, such as CD40-CD40L or ICOS-ICOS ligand are important determinants of B-cell-T-cell interactions that may be implicated in SLE (Dörner et al, 2016).

3.2 Organ-specific disease mechanisms and tissue damage

In SLE patients, potentially predisposing genetic loci for lupus nephritis (LN) and for central nervous system (CNS) involvement were identified (Chung et al, 2014; Ho et al, 2016a). The pathogenesis underlying different lupus disease activity and organ damage features is varied.

Anti-dsDNA antibodies are considered central to the pathogenesis of LN and integrate immune complexes that deposit in the kidney. Glomerular immune complexes mostly form *in situ* by binding of autoantibodies to nucleosomes from renal cells. Potential intrarenal sources of nucleosomes include neutrophils releasing NETs. Anti-dsDNA and immune complexes activate endothelial and mesangial cells and the complement system, driving inflammation through a variety of mechanisms. Cytotoxic T cells, Th17 cells as well as B cells and macrophages infiltrate the kidney in LN. A large number of mediators, including cytokines, chemokines and adhesion molecules, expressed by infiltrating and activated renal cells amplify the inflammatory process and collude to inflict progressive damage (Lech et al, 2013).

Exposure to ultraviolet light (UV) is a major trigger to development of lupus skin lesions. UV causes apoptosis of keratinocytes, and there is an accumulation of apoptotic keratinocytes in the epidermis of patients with lupus skin lesions (Deng et al, 2015). This may precipitate the immunopathogenic events leading to inflammatory skin lesions in SLE patients and, hypothetically, to systemic flares. Deposits of immune complexes, immunoglobulins and complement can be found along the dermoepidermal junction in sun-exposed non-lesional skin specimens of most SLE patients (the 'Lupus band').

A dysfunction of the blood-brain barrier may play a pivotal role in the pathogenesis of CNS lupus, allowing autoantibodies, soluble mediators and immune cells to abnormally reach the brain tissue. Autoantibodies may have a direct pathogenic role in CNS lupus, which is best established for antiphospholipid antibodies, but others, including anti-ribosomal P and anti-neuronal antibodies may also be implicated (Ho et al, 2016b). Many of the CNS lupus manifestations can be the end result of different pathogenic insults. Neuropsychiatric lupus is a highly heterogeneous group of clinical syndromes and may result from a wide variety of pathogenic mechanisms that is poorly understood.

4 Clinical features

4.1 Mucocutaneous features

Mucocutaneous involvement is one of the commonest clinical manifestations in SLE patients. These includes both lupus-specific and non-specific lesions (table 1) (Kuhn et al, 2014*; Okon et al, 2013).

4.1.1 Acute lupus-specific mucocutaneous lesions

The classic lupus ‘butterfly’ or malar rash presents acutely as a fixed, confluent, sharply outlined erythema, flat (macular) or raised (maculopapular) lesion, located at the malar eminences and over the nose, tending to spare the nasolabial folds. It can be pruritic, especially the papular lesions. It may evolve with fine scaling, erosions and crusts (figure 2A). Typically, acute cutaneous lupus erythematosus (ACLE) resolve over the course of days or weeks, without scarring. Malar rash was reported in 20-60% of large SLE cohorts (Cervera et al, 2003; Inês et al, 2015*). Differential diagnosis can be challenging and includes sunburn, polymorphous light eruption, facial flushing, telangiectasias, acne rosacea, seborrheic dermatitis, atopic and contact dermatitis, and glucocorticoid-induced dermal atrophy (Okon et al, 2014). Besides malar rash, ACLE lesions may present localized on the dorsa of the fingers and hands with periungual erythema but typically sparing the knuckles. Patients may also develop a more generalized maculopapular lupus rash (figure 2B).

Both localized and generalized ACLE are commonly, but not always, precipitated by exposure to sunlight or other sources of UV radiation, and in that case involve exposed skin areas. For SLE classification purposes, the ACR revised classification criteria for SLE (1997) defines the photosensitivity criterion as a skin rash resulting from unusual reaction to sunlight (by patient history or physician observation). In lupus patients without previous history of photosensitivity, risk associated with sunlight exposure is difficult to predict, even with photo testing procedures (Kuhn et al, 2010). The SLICC classification criteria for SLE (2012) redefined photosensitivity as an (acute) ‘photosensitive lupus rash’ and extended the scope of ACLE features for classification purposes, to include (acute) ‘maculopapular lupus rash’ (figure 2) and the rare manifestations ‘toxic epidermal necrolysis variant of SLE’ and ‘bullous lupus’. It also newly included the subacute cutaneous lupus lesions (Petri et al, 2012a*).

Table 1 Classification of lupus-associated mucocutaneous lesions

LE specific lesions	LE non-specific lesions
Acute cutaneous LE	Cutaneous vascular disease
Localised	Vasculitis
Generalised	Leucocytoclastic
Subacute cutaneous LE	Palpable purpura
Annular	Urticarial vasculitis
Papulosquamous (psoriasiform)	Polyarteritis nodosa-like
Chronic cutaneous LE	Vasculopathy
'Classic' DLE	Dego's disease-like
Localised	Atrophy blanche-like
Generalised	Periungual telangiectasia
Hypertrophic (verrucous) DLE	Livedo reticularis
Lupus panniculitis (profundus)	Thrombophlebitis
Mucosal LE	Raynaud's phenomenon
Lupus tumidus	Erythromelalgia
Chilblain lupus	LE non-specific bullous lesions
Discoid lupus/lichen planus overlap	Epidermolysis bullosa acquisita-like
	Dermatitis herpetiformis-like
	Pemphigus erythematosus
	Bullous pemphigoid
	Porphyria cutanea tarda
	Mucosal ulcerations
	Papulonodular mucinosis
	Anetoderma/cutis laxa
	Acanthosis nigricans
	Erythema multiforme
	Leg ulcers
	Lichen planus
	Alopecia (non-scarring)
	'Lupus hair'
	Telogen effluvium
	Alopecia areata
	Sclerodactyly
	Rheumatoid nodules
	Calcinosis cutis
	Urticaria

DLE, discoid lupus erythematosus; LE, lupus erythematosus.

Figure 3 *Acute cutaneous lupus erythematosus.*

A

B

(A) Localised (malar rash) and (B) diffuse (maculopapular rash).

4.1.2 Subacute lupus-specific mucocutaneous lesions

Subacute cutaneous lupus erythematosus (SCLE) is not uniformly associated with SLE (Okon et al, 2014). Patients with purely cutaneous lupus or with primary Sjögren's syndrome may also develop SCLE. About 50% of affected patients have SLE and about 10% of patients with SLE have this type of skin lesion (Wollina et al, 1999). Patients with SCLE have a high incidence of photosensitivity and lesions characteristically develop in sun-exposed areas (upper back, shoulders, extensor aspects of the arms, V-area of the neck, and less frequently on the face). SCLE lesions begin as erythematous macules or papules that evolve into scaly, papulosquamous (psoriasiform) or annular form. The latter often coalesce to form polycyclic plaques (figure 3). A few patients develop both types.

The central areas of annular SCLE lesions typically become hypopigmented. Differential diagnosis includes psoriasis, erythema multiforme and erythema annulare centrifugum. Lesions typically heal without scarring, although they can leave long-lasting or even permanent depigmentation and telangiectasias. Patients with active SCLE may also present coexisting acute and chronic mucocutaneous lesions. Subacute cutaneous lupus erythematosus has been associated with anti-Ro/SSA antibodies, genetic deficiencies in C2/C4, and certain drugs, such as hydrochlorothiazide.

4.1.3 Chronic lupus-specific mucocutaneous lesions

The most common feature of chronic rashes in SLE is classic discoid lupus erythematosus (DLE) that develop in up to 25% of patients with SLE (Pistiner et al, 1991). Patients with DLE have approximately a 5–10% risk of developing SLE, which tends to be mild. Risk is even higher with numerous and widespread skin lesions (Okon et al, 2014). DLE lesions start as flat or slightly elevated and well demarcated erythematous, scaly, macules or papules. These frequently evolve into larger, round ('discoid') infiltrated plaques covered by a well-formed adherent scale that extends into dilated hair follicles (follicular plugging) (figure 4). DLE commonly presents on the face, neck, extensor aspects of the arms and the scalp, but also occurs on the ears, and infrequently on the upper torso. DLE lesions slowly expand with active inflammation at the periphery and then heal, leaving depressed central scars, atrophy, telangiectasias and depigmentation (hyper- or hypopigmentation). Involvement of the hair follicles is a prominent feature of DLE and may lead to permanent hair loss, resulting in scarring alopecia. DLE occurring only on the head and neck is referred to as 'localized DLE', whereas lesions both above and below the neck is named 'generalized DLE'. Lesions solely below the neck are rare. DLE can be precipitated by UV exposure or any form of skin trauma. The differential diagnosis includes a variety of disorders that can clinically simulate some phases of DLE, such as polymorphous light eruptions, psoriasis, actinic keratosis, sarcoidosis, and tertiary syphilis. The histopathology usually distinguishes these conditions from DLE. In the ACR classification criteria, only the classic DLE was included as a criterion, while in the newer SLICC classification set, other chronic LE-specific features are also counted.

In rare cases, DLE can present with very prominent hyperkeratosis, which is named hypertrophic DLE. Very infrequently, lesions can have overlapping features with lichen planus (discoid lupus/lichen planus overlap).

Lupus erythematosus profundus or lupus panniculitis is characterised by inflammatory lesions in the lower dermis and subcutaneous tissue. It presents in up to 3% of SLE patients. Clinically it presents as deep, firm nodules, 1 to 3 cm in diameter, with or without overlying superficial lesions and are often painful. They usually appear on the scalp, face, arms, chest, back, thighs and buttocks. As the lesions mature, the overlying skin progressively becomes attached to the subcutaneous nodules, producing saucerized depressions with areas of scarring skin atrophy.

Chilblain lupus is precipitated by cold exposure, presenting as red-purple patches and plaques involving most frequently fingers and toes during the winter season. As the lesions mature, they can take the typical clinical aspect of DLE. These lesions are sometimes named ‘perniosis lupus erythematosus’, that is distinct from ‘lupus perniosis’ (a form of cutaneous sarcoidosis).

Lupus tumidus, a rare variant, is characterised by succulent, oedematous, urticaria-like plaques occurring in sun-exposed skin.

Mucosal membranes can be involved in DLE, most frequently in the mouth (buccal, palate, alveolar processes, tongue, lips), and more rarely in the nasal, conjunctival and genital mucosae. Lesions begin as painless erythematous patches and mature into chronic DLE plaques which may be hard to distinguish from oral lichen planus. Involvement of the nasal mucosa can rarely cause perforation of the nasal septum.

Bullous lesions rarely develop in SLE, as a result of dissolution of the basal cell layer with sub epidermal cleavage plane, within lesions with lupus-specific skin histopathology. These bullous presentation may occur in acute or subacute cutaneous lupus (‘toxic epidermal necrolysis variant ACLE and SCLE’ and ‘vesiculobullous annular SCLE’) and as bullous DLE. In addition, there are also several LE non-specific bullous lesions that can present in SLE.

Figure 4 Subacute cutaneous lupus lesions.

Figure 5 Facial discoid lupus rash with a malar distribution.

Erythema, keratin plugged follicles and dermal atrophy. The typical pattern of hyperpigmentation at the active border and hypopigmentation at the inactive centre is particularly evident in black patients. DLE in the face usually spares the nasolabial folds and must be differentiated from acute malar rash. (Patient consent obtained)

4.1.4 Pathology of lupus-specific mucocutaneous lesions and the 'lupus band test'

Histopathology of lupus-specific skin lesions presents characteristic features including mononuclear cell infiltration around the dermal-epidermal junction, dermal oedema, hyperkeratosis and basal cell degeneration. These features are present in ACLE, SCLE and DLE, so that it may be impossible to differentiate between them from histopathology. Skin biopsy samples of non-lesional, sun-protected areas from SLE patients can present the 'lupus band' of immunoglobulins and complement components, including the membrane attack complex (C5b through C9) at the dermal–epidermal junction (Biesecker et al, 1982). This positive non-lesional 'lupus band test' may be of diagnostic usefulness in selected cases, considering it has a fairly good specificity but a limited sensitivity.

4.1.5 Lupus erythematosus non-specific mucocutaneous lesions

A wide variety of non-specific mucocutaneous lesions can be found in SLE patients, some of them with high prevalence (i.e., photosensitivity, oral and nasal ulcers, Raynaud's phenomenon, non-scarring alopecia). Despite the lack of specificity, some of these are included in the SLICC lupus classification criteria (i.e., photosensitivity, oral and nasal ulcers, non-scarring alopecia). Furthermore, some of these features are included in SLE disease activity indexes, such as the SLEDAI and BILAG index, and cutaneous vasculitis heavily weights the disease activity score in SLEDAI. In clinical practice, correct attribution of these lesions to SLE or other causes is frequently challenging, and of utmost importance for appropriate management decisions.

Photosensitivity is defined as the development of an inflammatory rash after exposure to UV-B radiation coming from sunlight or fluorescent lights that may last several days or even weeks. It occurs in 60–100% of patients with SLE. Some patients are also sensitive to UV-A radiation. The clinician should be wary of diagnosing photosensitivity based on history alone, and other causes or mimics must be considered.

Livedo reticularis can present in SLE patients, as a mottled reticulated purplish pattern on the arms and legs (figure 5 A), caused by swelling of the venules in the skin. It is frequently aggravated by cold exposure, similarly to the more frequent Raynaud's phenomenon.

Cutaneous vasculitis, usually a small vessel vasculitis, can present in SLE with a variety of lesions, such as punctuate lesions, erythematous plaques or macules, urticaria-like lesions, periungual erythema (figure 5 B), splinter nailfold haemorrhages, palpable purpura, ulcerations, digital gangrene, and cutaneous infarctions. Cutaneous vasculitis may be associated with systemic vasculitis. Ulcerations and gangrene may also result from secondary antiphospholipid syndrome.

Non-scarring alopecia, defined as diffuse thinning or hair fragility with visible broken hairs, occurs in most patients with SLE (Yun et al, 2007). Clinically observed diffuse hair thinning results from a synchronization of hair shedding, often with an acute onset (telogen effluvium), which is a reactive process caused by a systemic lupus flare, an acute illness, hormonal or physical stress. Diffuse lupus-related alopecia is typically self-limited and the hair spontaneously returns to normal after reduction of the underlying SLE activity. Hair fragility with visible broken hairs is denominated 'lupus hair' and is frequently seen with lupus-related alopecia. As with photosensitivity, the clinician should be wary of diagnosing lupus-related alopecia based alone in a subjective history of exaggerated hair loss. It must be differentiated from the usually patchy and potentially scarring alopecia accompanying discoid lupus in the scalp.

Mucosal ulcers occur in 25–45% of patients (Khatibi et al, 2012). Most commonly present on the soft or hard palate or buccal mucosa, but they may also involve the nasal and upper airway mucosa (Jonsson et al, 1984). These mucosal ulcers usually resolve without scarring. Differentiation from mucosal DLE should be made. Oral ulcers in SLE are usually asymptomatic; by contrast, those not lupus-related are commonly quite painful. Differential diagnosis of ulcers attributable to SLE disease activity from other conditions is challenging, including lichen planus, candidiasis, aphthous stomatitis, intraoral herpes, Behçet's disease, bite marks, leucoplakia and malignancy.

Figure 6 (A) Livedo reticularis and (B) periungual erythema.

4.2 Musculoskeletal features

The musculoskeletal system is affected in 53–95% of patients with SLE. These features, especially lupus arthritis, are frequently the first clinical manifestation of SLE. It is a particularly common presenting manifestation motivating referral to rheumatology. Many of these patients do not have at presentation any clinical manifestations from other organ systems; however, appropriate laboratory tests may reveal other, often asymptomatic but potentially severe organ involvement, such as lupus nephritis. Some patients may present at early arthritis clinics with undifferentiated arthritis that with time will evolve in to SLE. In young women presenting with arthritis, the differential diagnosis should include SLE.

4.2.1 Lupus arthritis

Joint involvement is typically non-erosive, non-deforming inflammatory arthritis primarily affecting the small joints of the hands (especially the proximal interphalangeal joints), wrists and knees, most frequently as a polyarthritis (Grossman 2009). It may first present at clinical onset of SLE or at any time during the disease course. Patient's symptoms (inflammatory pain and morning stiffness) are usually more prominent than the synovitis on physical examination, which is usually mild. Lupus arthritis is often evanescent, but tends to be recurrent. A few patients have a chronic polyarthritis with a pattern indistinguishable from rheumatoid arthritis (sometimes called 'rhumus'). Patients with chronic polyarthritis are more prone to develop joint deformities, in particular Jaccoud-type arthropathy similar to rheumatoid arthritis hand deformities except that the deformities are usually reducible and due to ligamentous laxity and not to bony damage (figure 6). In rare cases, lupus arthritis is erosive and most of these patients have positive anti-cyclic citrullinated peptide antibodies (anti-CCP). In a meta-analysis, estimated sensitivity and specificity of anti-CCP for erosive arthritis in SLE patients was 47.8% and 91.8%, respectively (Budhram et al, 2014).

Diagnosis of lupus arthritis may be challenging, due to the frequently mild synovitis. Clinicians should be wary of diagnosing it solely based on patient history, when objective synovitis is not found at clinical examination. Alternative causes must be ruled out, including fibromyalgia and in older patients, flares of osteoarthritis.

Tenosynovitis may be an early manifestation and tendon rupture can occur. Subcutaneous nodules similar to rheumatoid nodules can be rarely found in SLE. Chest pain or discomfort secondary to costochondritis has been reported. Relapsing polychondritis can also occur.

Figure 7 Jaccoud-type (deforming) arthropathy.

(Courtesy of Dr D Vassilopoulos).

4.2.2 Myositis

Generalised myalgia and muscle tenderness are common during disease exacerbations and should be differentiated from fibromyalgia complaints. Inflammatory myositis affecting the proximal muscles has been reported in 4–16% of adult patients and in up to 31% of paediatric SLE patients and may develop at any time during the course of the disease (Record et al, 2011). Myopathy caused by exposure to statins, glucocorticoids, antimalarials or other drugs should be excluded.

4.2.3 Avascular bone necrosis

Avascular necrosis of bone is an important cause of morbidity and disability in SLE, which occurs in 5% to 10% of patients. Acute or subacute localized joint pain, most often in shoulders, hips and knees, may indicate avascular necrosis. MRI is useful for early diagnosis and differentiating from other causes such as synovitis and osteoarthritis. Factors that can induce bone ischaemia and necrosis include Raynaud's phenomenon, vasculitis, fat emboli, glucocorticoids and the antiphospholipid syndrome. Osteonecrosis often develops shortly after the onset of high-dose glucocorticoid therapy.

4.2.4 Osteoporosis and fragility fractures

Factors contributing to increased risk of osteoporosis and fragility fractures in SLE include the disease activity, lupus damage (such as chronic renal failure), low vitamin D due to sun avoidance and use of sunscreens (advised for photosensitivity), medications (glucocorticoids in particular), and traditional risk factors in a mostly female population (Carli et al, 2016).

4.3 Renal features

4.3.1. Epidemiology

Lupus nephritis (LN) is the most frequent major organ involvement in SLE patients. Approximately 50% of patients with SLE develop LN during the disease course, with about 15-20% presenting with LN at time of SLE diagnosis. It is an important cause of morbidity and reduced survival of SLE patients (Cervera et al, 2003). In paediatric-onset SLE, risk of LN is higher and its prognosis more severe (Amaral et al, 2014). Patients with non-European ancestry (African-Americans, African-Caribbean, American-Hispanics and Asian ethnicities) present with LN more frequently and are more likely to develop renal damage than patients of European descent (Korbet et al, 2007). LN can progress to chronic renal failure requiring dialysis and renal transplantation.

4.3.2. Clinical diagnosis with indication for renal biopsy

The most frequent presenting manifestation of LN is proteinuria, usually without evident clinical signs of renal disease. This poses important diagnostic challenges, particularly when LN is an inaugural feature of SLE. Patients with newly active LN, either inception SLE cases or those with established disease, may or may not present any concomitant clinical manifestations of SLE. An early diagnosis of LN is of paramount importance for initiating timely and appropriate treatment, in order to optimize prognosis. A dipstick urinalysis is a readily available screening tool, with abnormalities requiring confirmation by other tests. Urinalysis must be systematically done in the diagnostic workup of suspected SLE and in every clinical assessment of SLE patients.

A diagnosis of LN is defined in SLE patients as urinary findings of: (i) persistent proteinuria >0.5 g per day in a 24-hour urine collection or a spot urine sample protein/creatinine ratio >0.5 , and/or (ii) 'active urinary sediment' (>5 red blood cells /high-power field (hpf) and/or >5 white blood cells/hpf in the absence of infection, and/or cellular casts of red or white blood cells) (Dooley et al, 2004). The ACR classification criteria for SLE rely in these findings for case definition of LN and do not require a renal biopsy for classification purposes. However, current ACR and EULAR guidelines recommend that all patients with clinical/analytical signs of active LN previously untreated undergo renal biopsy (unless strongly contraindicated) (Bertsias et al, 2012*; Hahn et al, 2012).

Proteinuria >0.5 g/day is an almost universal finding in active LN cases, ranging from low levels (<1.0 g/day) to >3.5 g/day (with nephrotic syndrome). Microscopic findings of 'active urine sediment' are less frequently found, and when present are almost invariably associated with proteinuria. Nevertheless, a renal biopsy may also be considered in the rare cases of SLE patients with unexplained persistent microscopic haematuria or leukocyturia, or elevated serum creatinine but without proteinuria >0.5 g/day (Bertsias et al, 2012*). Alternative causes for haematuria (i.e. menses, renal stones) and leukocyturia (i.e. urinary or gynaecological infection) should be excluded. Due to its convenience, the urinary protein excretion is most frequently gauged in the clinical practice in a random daytime spot urinary sample using the protein/creatinine ratio for quantification. It is however subject to spurious fluctuations, which may be contributed by orthostatic proteinuria and associated with changes in physical activity; to reduce these effects, a sampling of first morning urine may be more reliable. The 24-hour urine collection is also subject to spurious variations, in particular due to incomplete collections and changes in physical activity; quantification of creatinine excretion in the same sample can help appreciate if the collection was complete (Saxena et al, 2011). In clinical practice, when there is doubt if the proteinuria quantification was correct, a second confirmatory sampling, possibly using an alternative method, should be considered.

Some blood tests are useful in the diagnosis and monitoring of LN. Anti-dsDNA antibodies are usually high and complement levels of C3 and C4 low in patients with active LN, although this is not always the case. In longitudinal follow-up of SLE patients, increasing levels of anti-dsDNA and decreasing levels of C3 and C4 may precede a LN (or extra-renal) flare, justifying tighter monitoring of these patients. However, their accuracy is low. Other biomarkers, in particular anti-C1q antibodies, were associated with LN and their use in a combined panel of biomarkers may in the future improve the diagnosis and monitoring of LN (Orbai et al, 2015). Monitoring of blood pressure, serum creatinine, estimated glomerular filtration rate, albumin, and complete blood cell count is recommended in patients with LN (Bertsias et al, 2012*). Antiphospholipid antibodies should also be tested, as they can cause a distinct nephropathy (thrombotic microangiopathy), with different treatment requirements.

4.3.3. *Differential diagnosis of LN*

A variety of nephropathies other than LN can present with similar clinical and analytical features in SLE patients. The epidemiological and clinical context may help to raise suspicion of the appropriate alternative diagnosis. In some patients, other causes of nephropathy can coexist with LN. In patients with previous LN, an increased proteinuria and/or deteriorating renal function are not always due to a LN flare or related renal scarring, and appropriate alternative diagnosis should be considered.

Differential diagnosis of LN include tubule-interstitial nephritis, diabetic nephropathy, drug-induced nephrotoxicity, thrombotic microangiopathy associated with antiphospholipid syndrome, haemolytic-uremic

syndrome, preeclampsia (in pregnancy), hypertensive nephrosclerosis, or arterionephrosclerosis (Giannico et al, 2013*).

4.3.4. Renal histopathology

Renal biopsy is fundamental to confirm the LN diagnosis and exclude other causes of nephritis, establish the histopathological type of LN to guide treatment and estimate prognosis (Giannico et al, 2013*; Bertias et al, 2012*). Clinical and analytical results do not accurately reflect the histopathologic type and severity of LN. Even patients with low levels of proteinuria (0.5-1.0 g/day) may present significantly active LN (Christopher-Stine et al, 2007). Renal biopsy is usually well tolerated and carries only a small risk of bleeding and perirenal hematoma.

For pathological assessment of renal biopsy, the sample should include ≥ 8 glomeruli, to be examined under light microscopy (haematoxylin/eosin, periodic acid-Schiff, Masson's trichrome and silver stain), and include immunofluorescence or immunohistochemistry for immunoglobulin and complement deposits. Electron microscopy, if available, can be useful (figure 7) (Bertias et al, 2012*).

Figure 8 Electron microscopy demonstrating subendothelial deposition of electron-dense immune complexes in proliferative lupus nephritis.

Electron microscopy helps to define distribution (subendothelial, epithelial, membranous deposits) of immune complexes and may be useful in the recognition of early proliferative changes when the light microscopy findings are subtler.

Histopathology of LN is currently classified using the 'International Society of Nephrology / Renal Pathology Society classification' (ISN/RPS) (Table 2; Figure 8) (Weening et al, 2004): Class I (minimal mesangial immune deposits on immunofluorescence with normal light microscopy); class II (mesangial hypercellularity or matrix expansion with immune deposits confined to mesangium); class III (subendothelial immune deposits and

proliferative changes in <50% of glomeruli); class IV (same as class III, with changes in >50% of glomeruli); class V (sub epithelial immune deposits and membranous thickening of glomerular capillaries); class VI (sclerosis of $\geq 90\%$ of glomeruli). There are also complex LN cases with combined class III or IV with V. Prognosis is best for classes I-II, but proliferative LN (classes III and IV) are the most prevalent. Class VI represents progression from other classes to end stage renal scarring. In repeat renal biopsies during subsequent flares of LN, some patients present a clinically relevant switch from non-proliferative to proliferative LN, while the opposite is uncommon (Daleboudt et al, 2009).

Figure 9 ISN/RPS histopathological classes of lupus nephritis.

(A) Minimal mesangial LN (class I). (B) Mesangial proliferative LN (class II). (C) Focal LN (class III) and Diffuse LN (type IV). (D) Membranous LN (type V).

Table 2 The 2003 ISN/RPS Classification of lupus nephritis (LN)

Class I	Minimal mesangial LN
Class II	Mesangial proliferative LN
Class III	Focal LN (<50% of glomeruli) (A, C or A/C)
Class IV	Diffuse LN (>50% of glomeruli) (A, C or A/C, and S versus G)
Class V	Membranous LN
Class VI	Advanced sclerotic LN (≥90% of glomeruli globally sclerosed without residual activity)

A: active lesions; C: chronic lesions; A/C: active and chronic lesions; S: segmental; G: global

In addition to the diagnosis of glomerular disease according to ISN/RPS classes, tubulointerstitial and vascular changes should be evaluated. In cases with proliferative LN (Class III and IV), lesions should be scored as active (A) (*i.e.*, endocapillary proliferation, fibrinoid necrosis, and cellular crescents), chronic (C) (*i.e.*, sclerosis, fibrous crescents, and interstitial fibrosis) or combined A/C. The class IV is further classified as segmental (S) (<50% of the glomerular tuft involved) or global (G) (>50% of the glomerular tuft). Some studies suggest a differential prognostic value for these categories, although it remains controversial (Giannico et al, 2013*). Renal vascular lesions, including thrombotic microangiopathy, lupus vasculopathy and lupus necrotizing vasculitis are not frequent, but carry an increased risk of progression to chronic renal failure (Banfi et al, 1991).

4.4 Nervous system features

Neuropsychiatric (NP) manifestations in SLE include a wide range of neurologic and psychiatric features (Hanly et al, 2010*). The ACR established a widely used nomenclature system with detailed case definitions for the neuropsychiatric manifestations seen in SLE (ACR, 1999*). Importantly, these do not imply attribution to SLE-related pathogenesis. Therefore, a complete clinical assessment and appropriate investigations should be used to diagnose NP events and establish its aetiology to SLE or non-SLE causes and particularly to exclude infection (fig. 9) (Bertsias et al, 2010a*). Regardless of attribution, NP manifestations result in decreased quality of life, work disability and increased unemployment (Hanly et al, 2010*). Current therapeutic strategies are largely empiric, based on known immunopathogenetic mechanisms and observational studies (Hanly et al, 2014). For a comprehensive review on this topic, access the In-depth discussion I (Neuropsychiatric Manifestations in SLE).

Figure 10 Severe neuropsychiatric lupus.

MRI imaging showing cerebrovascular disease (A and B); thrombosis in the sagittal sinus in a patient with antiphospholipid antibodies (C); and acute transverse myelitis (D).

4.5 Cardiovascular features

Pericarditis occurs in 15–25% of patients with SLE. Pericardial effusions may be asymptomatic and are usually mild to moderate.

Myocardial involvement is rare and typically occurs in the presence of generalized lupus activity. The patient may present with fever, dyspnoea, tachycardia and congestive heart failure. Features of left ventricular dysfunction, non-specific ST/T wave changes, segmental wall motion abnormalities and decreased ejection fraction are found in >80% of patients with myocarditis. MRI has been used to detect both clinical and subclinical myocardial involvement in SLE.

Valvular heart disease is common in SLE and has been linked to antiphospholipid antibodies. The most frequent abnormality is diffuse thickening of the mitral and aortic valves followed by vegetations, valvular regurgitation and stenosis, in decreasing order of frequency. The combined incidence of stroke, peripheral embolism, heart failure, infective endocarditis and the need for valve replacement is about threefold higher in patients with valvular disease than in those without it. Pathological studies have shown active and healed valvulitis, as well as active Libman–Sacks vegetations with acute thrombus, healed vegetations with or without hyalinised thrombus, or both active and healed vegetations, in the same or different valves.

Patients with SLE have increased morbidity and mortality from cardiovascular disease. This includes accelerated, premature atherosclerosis and valvular heart disease. Studies have shown increased risk for myocardial infarction or stroke in lupus patients with significant risk of premature death and this risk cannot be fully explained by the traditional cardiovascular disease risk factors (Yee et al, 2015*).

4.6 Pleura and lungs features

The most common pleuropulmonary manifestation of SLE is pleuritis (table 3) (Mittoo et al, 2014). Pleuritic pain may occur with or without pleural effusion, with clinically apparent pleural effusions reported in up to 50%, but are usually mild and transient. Effusions are frequently bilateral, equally distributed between the left and right hemithoraces. The effusion is exudative with higher glucose and lower lactate dehydrogenase levels than those found in rheumatoid arthritis.

Clinically significant interstitial lung disease complicates SLE in 3–13% of patients and may be severe. It can rarely present as acute pneumonitis with cough, dyspnoea, pleuritic pain, hypoxaemia and fever. Chest radiographs show unilateral or bilateral infiltrates. Fibre optic bronchoscopy with bronchoalveolar lavage and transbronchial lung biopsies is usually needed to establish the diagnosis of interstitial lung disease and to exclude infection. Pulmonary hypertension is a rare and severe feature, most frequently presenting with dyspnoea.

Pulmonary haemorrhage is a rare but potentially life-threatening complication of SLE, requiring emergency care. Clinical features are non-specific, with diffuse alveolar infiltrates, hypoxaemia, dyspnoea and anaemia. The 'shrinking lung syndrome' is a rare and enigmatic feature, further discussed in the in-depth discussion II.

Table 3 Pleuropulmonary manifestations of SLE

Pleuropulmonary manifestation	Presentation
Pleuritic chest pain or pleurisy	Common
Pleural effusion	Exudate; unilateral or bilateral
Acute pneumonitis	Uncommon; presentation includes: fever, non-productive cough, infiltrates, hypoxia; high mortality rates
Interstitial lung disease	Insidious onset of dyspnoea on exertion, non-productive cough, pleuritic chest pain
Bronchiolitis obliterans with organising pneumonia	Can be difficult to diagnose; requires biopsy; responds to glucocorticoids
Pulmonary capillaritis or diffuse alveolar haemorrhage	Rare, associated with antiphospholipid antibodies; poor prognosis
Shrinking-lung syndrome	Uncommon; presentation includes: dyspnoea on exertion, pleuritic chest pain
Pulmonary embolism or infarction	Usually in patients with antiphospholipid antibodies
Pulmonary hypertension	Insidious onset of dyspnoea on exertion, chronic fatigue, weakness, palpitations, oedema
Lymphadenopathy	Massive mediastinal lymphadenopathy uncommon in patients with SLE alone. Cervical and axillary common, correlates with disease activity
Infection	Typical and atypical pathogens. Due to immune dysfunction (low CD4 lymphocytes) and immunosuppressive drugs
Malignant tumour	Lung cancer especially in smokers; lymphoma

4.7 Lymphadenopathy and splenomegaly

Lymphadenopathy occurs in about 40% of patients, usually at the onset of disease or during disease flares (Shapira et al, 1996). Lymph nodes are typically soft, non-tender, discrete but fluctuating in size and are usually detected in the cervical, axillary and inguinal area. Clinically significant lymphadenopathy that raises diagnostic problems is less common. Patients with lymphadenopathy are more likely to have constitutional symptoms. A lymph node biopsy may be warranted when the degree of lymphadenopathy is out of proportion to the activity of the lupus especially with persistent fever, sweats and weight loss. It is important to consider lymphoma and tuberculosis in the differential diagnosis. Splenomegaly occurs in 10–45% of patients, particularly during active disease and is not necessarily associated with cytopenias. Splenic atrophy and functional hyposplenism have also been reported in SLE and may predispose to severe septic complications.

4.8 Haematological features

Haematological abnormalities are common and can be the presenting symptom or sign in SLE, especially lymphopenia. Major clinical manifestations include haemolytic anaemia, leukopenia, thrombocytopenia and thrombophilia due to antiphospholipid antibodies.

4.8.1 Anaemia

Anaemia in SLE is common and, depending on the cause, can correlate or not with SLE disease activity: some cases are SLE-related but most are not. The most frequent causes are iron deficiency anaemia and anaemia of chronic disease. Other less common causes include haemolysis (autoimmune or microangiopathic), chronic renal failure, drugs, infection, hypersplenism, myelodysplastic syndrome, myelofibrosis and aplastic anaemia.

Blood loss, either from the gastrointestinal tract (frequently secondary to non-steroidal anti-inflammatory drugs), or due to excessive menstrual bleeding commonly cause iron-deficiency anaemia. Suppressed erythropoiesis from chronic inflammation related to SLE disease activity may also cause anaemia. Autoimmune haemolytic anaemia was reported much less frequently, in up to 10% of patients; of note, patients with SLE may have a persistently positive direct Coombs' test without haemolysis. A microangiopathic haemolytic anaemia with or without the other features (fever, thrombocytopenia, kidney involvement and/or neurological symptoms) of thrombotic thrombocytopenic purpura (TTP) has been reported in SLE patients. The presence of schistocytes in the peripheral blood smear and increased lactate dehydrogenase levels are the hallmarks of this disorder which has a high mortality and warrants urgent plasma exchange. A similar syndrome can also occur in the presence of antiphospholipid antibodies. Red cell aplasia due to antibodies against erythrocyte progenitors has been rarely reported in patients with SLE.

4.8.2 Leukopenia and lymphopenia

Leukopenia is common in SLE; it can be the presenting symptom and is usually associated with disease activity. A white blood cell count $<4000/\text{mm}^3$ has been reported in up to 30–40% of patients, especially in presence of active disease, but it is usually mild. Severe leukopenia with neutrophil count $<500/\text{mm}^3$ is rare but carries a high risk of infection. Lymphopenia (variously defined as lymphocyte count $<1500/\text{mm}^3$ or $<1000/\text{mm}^3$) occurs in most patients with SLE and is frequently proportional to disease activity.

4.8.3 Thrombocytopenia

Mild thrombocytopenia ($50\,000$ – $100\,000/\text{mm}^3$) was reported in 25–50% of patients and is often associated with antiphospholipid syndrome; clinically significant thrombocytopenia ($<50\,000/\text{mm}^3$) with a risk of bleeding occurs in less than 10%. The most common cause of thrombocytopenia in SLE is immune-mediated platelet destruction, but increased platelet consumption may also occur owing to microangiopathic haemolytic

anaemia or hypersplenism. Impaired platelet production secondary to drug treatment is another possible contributing factor. Some patients present with autoimmune thrombocytopenia, especially in childhood, as a feature of undifferentiated connective tissue disease, with anti-nuclear antibodies, and years later may evolve to SLE.

4.8.4 *Thrombophilia*

Thrombosis may be the presenting feature of SLE with antiphospholipid syndrome or develop later during the SLE disease course. Antiphospholipid syndrome is discussed in another module.

4.9 Liver and gastrointestinal tract features

4.9.1 *Gastrointestinal tract*

Gastrointestinal (GI) manifestations are reported in 25–40% of patients with SLE, and commonly represent non-SLE related features, drug adverse events or more rarely, SLE GI involvement (Ebert et al, 2011).

Dyspepsia has been reported in 11–50% of patients, and peptic ulcers (usually gastric) in 4–21%. Xerostomia is relatively frequent and can be due to associated Sjögren's syndrome.

4.9.2 *Abdominal pain*

Abdominal pain may be the presentation of rare SLE-related conditions such as peritonitis, mesenteric vasculitis, intestinal infarction, and pancreatitis. The clinical presentation is usually an insidious abdominal pain that months later can evolve to an acute abdomen with nausea, vomiting, diarrhoea, GI bleeding and fever. Patients with acute presentation may also have peritonitis with or without ascites due to serositis (with or without pleuritic/pericarditis) or less commonly mesenteric thrombosis and infarction, often in association with antiphospholipid antibodies. Ascites is uncommon in SLE and, when detected, infectious causes and/or perforation must be excluded by paracentesis. Congestive heart failure and hypoalbuminaemia secondary to nephrotic syndrome or protein-losing enteropathy represent other possible causes of ascites in patients with SLE. Protein-losing enteropathy has been rarely described and can be the first manifestation of the disease. It usually occurs in young women and is characterized by oedema and hypoalbuminaemia. The diagnosis of mesenteric vasculitis is challenging and it is critical to exclude infection, for example diverticular abscess. Plain radiographic studies may show segmental bowel dilatation, air-fluid levels, 'thumb-printing' or narrowing of the lumen and pseudo-obstruction. Abdominal CT scan findings compatible with mesenteric vasculitis include prominence of mesenteric vessels with a comb-like appearance supplying dilated bowel loops, small bowel thickening and ascites. Vasculitis generally involves small arteries, so that angiography is frequently negative. Lupus pancreatitis may result from vasculitis or thrombosis and occurs in as many as 2–8% of patients.

4.9.3 Liver disease

The incidence of hepatomegaly is 12–25%. Steatosis is a common finding, commonly due to unrelated causes or secondary to glucocorticoids. Blood liver enzymes may be abnormal in patients with active disease or more frequently related to drug treatment or viral infections. An unrelated autoimmune hepatitis was in the past designed as ‘lupoid hepatitis’.

4.10 Ophthalmic features

Up to 8% of patients with SLE develop inflammation of the retinal artery during the course of their disease. An equal number of patients have infarction of the retinal vasculature secondary to antiphospholipid antibodies. Both conditions can lead to the presence of ‘cotton-wool’ spots in the retina visible on ophthalmoscopy or fluorescein angiography (where perivascular exudates and patches of dye leakage along the vessels are seen). Cotton-wool spots result from focal ischaemia and are not specific for lupus. Retinal vasculitis is usually associated with generalized active systemic disease and presents early in the disease process. Xerostomia is frequently found, as a feature of Sjögren’s syndrome associated with SLE, usually in patients with anti-SSA/SSB antibodies and may lead to corneal ulcers. Uveitis and scleritis are rare manifestations in SLE (<1% of patients). Optic neuritis is also rare.

5 Diagnosis

The “gold-standard” is a clinical diagnosis established by a clinician experienced in SLE, since there are no diagnostic criteria or any pathognomonic features. The clinical diagnosis is established based on the identification of several clinical and analytical features consistent with the diagnosis of SLE (described in the previous section), either concomitantly or cumulatively, while carefully considering other alternative explanations for the clinical picture.

5.1 Clinical presentation

The frequency of lupus manifestations in an international SLE inception cohort is presented in table 4 (Hanly et al, 2007). Possible combinations of clinical features are very heterogeneous, both at onset and during the disease course.

Table 4 Frequency of SLE manifestations defined according to ACR classification criteria in the SLICC inception cohort (n=572; mean disease duration \pm SD=5.2 \pm 4.2 months)

Cumulative ACR manifestations	%
Malar rash	37
Discoid rash	12
Photosensitivity	40
Oral/nasal ulcers	38
Serositis	27
Arthritis	74
Renal disorder	29
Neurologic disorder	5
Hematologic disorder	61
Immunologic disorder	76
Antinuclear antibody	95

5.2 Serological tests

5.2.1 Antinuclear antibodies (ANA)

The ANA assay is frequently used as screening test, in patients with a clinical picture suggestive of connective tissue disease, because of its very good sensitivity (>90% when using human cultured cells as the substrate) and wide availability. However, the specificity of ANA for SLE is low, since they are frequently found in many other conditions, as well as less frequently in the healthy population. Low serum titers (\leq 1:160) more frequently present without clinical significance. In contrast to the low positive predictive value of ANA testing, a patient with a negative test ($<$ 1:40) has less than a 3–5% probability of having SLE; thus, a negative ANA test is useful for excluding the diagnosis of SLE. However, when typical features of SLE are present, a negative ANA test cannot rule out the diagnosis (Bertsias et al, 2013). This is especially true for laboratories that employ enzyme immunoassays or other automated assays, which display marked inter-manufacturer variation in performance. In such cases, reported sensitivity against positive immunofluorescence-ANA with titre at 1:160 ranges from 70% to 98% (Meroni et al, 2010).

5.2.2 Anti-dsDNA antibodies

Antibodies to double-stranded (ds) DNA are found in about 70% of SLE patients at some point during the course of their disease, and are 95% specific for SLE. Their positivity may precede the clinical onset of the disease and are found in patients with undifferentiated connective tissue disease, some of whom will evolve to SLE. Clinical significance is more likely for moderate to high serum levels, taking into account the positivity cut-off of the assay used.

5.2.3 Antibodies to extractable nuclear antigens (ENA)

The main anti-ENA antibodies are: anti-Sm, anti-SSA(Ro), anti-SSB(La), anti-RNP, anti-topoisomerase I (Scl-70) and anti-Jo1. The ENA designation derives from its original identification in a saline extract of cell nuclei, despite that later it was found to include both nuclear and cytoplasmic proteins, which are associated with various RNA molecules. The anti-Sm antibodies are detected in 10–30% of lupus patients and are very specific for SLE. Anti-RNP antibodies, anti-SSA and anti-SSB are frequently found in SLE patients but are not disease specific.

5.2.4 Other auto-antibodies

Anti-ribosomal antibodies are specific for SLE but less sensitive than anti-dsDNA or anti-Sm antibodies. Anti-nucleosome antibodies were reported to present good sensitivity and specificity for SLE, but remain little used. Antiphospholipid antibodies can be quantified as anticardiolipin and anti-beta2-Glycoprotein I antibodies (IgG, IgM, and IGA) or indirectly detected in the lupus anticoagulant test; they are frequently found in SLE patients but are not specific. The anti-C1q antibody is associated with lupus nephritis. The direct antiglobulin (Coombs) test is positive in about 10% of SLE patients; is usually positive in those with autoimmune haemolytic anaemia but is not specific.

5.2.5 Serum complement levels

The complement system plays a major role in SLE pathogenesis and disease activity. The serum levels of complement fractions C3 and/or C4 are below normal in about 70% of SLE patients at some point during the disease course, frequently at the disease onset. Sensitivity of low C3 is higher than that of low C4 for SLE, and moderately specific. It is a widely available test, and in addition to its diagnostic value, longitudinal measurement of C3 and C4 serum levels can be useful for monitoring changes in disease activity (Leffler et al, 2014).

5.3 Differential diagnosis

Other diseases that must be frequently considered include undifferentiated connective tissue disease, rheumatoid arthritis, primary Sjögren's syndrome, primary antiphospholipid syndrome, fibromyalgia with positive ANA, idiopathic thrombocytopenic purpura, drug-induced lupus, and autoimmune thyroid disease. Patients with fever or splenomegaly/lymphadenopathy must be differentiated from those with infectious diseases or lymphoma. Lupus may present with lymphadenopathy or splenomegaly but the size of lymph nodes is rarely >2 cm, while splenomegaly is mild to moderate. Patients with known or suspected SLE with prominent lymphadenopathy, massive splenomegaly or expansion of a monoclonal CD19+/CD22+ B cell population should raise the suspicion of non-Hodgkin's lymphoma. In patients presenting with neurological symptoms, infections, cerebrovascular accidents or immune-mediated neurological diseases, such as multiple

sclerosis or Guillain–Barré disease, must be considered. Finally, in patients presenting with pulmonary-renal syndrome, the disease must be differentiated from Goodpasture’s syndrome, or antineutrophil cytoplasmic autoantibody (ANCA)-associated vasculitis. The differential diagnosis of glomerulonephritis includes post infectious glomerulonephritis (streptococcal, staphylococcal, subacute bacterial endocarditis or hepatitis C virus), membranoproliferative glomerulonephritis or renal vasculitis (ANCA or antiglomerular basement membrane (anti-GBM) associated).

Patients with undifferentiated connective tissue disease account for 10–20% of patients referred to tertiary care centres, and some of these will evolve to SLE or other differentiated systemic rheumatic disease, usually in the first 5 years after clinical onset. There are also patients with overlapping features of SLE and other connective tissue diseases. These syndromes are presented in another module of the EULAR course.

6 Classification criteria

Criteria for SLE classification were developed by the American College of Rheumatology (ACR) in 1971, and revised in 1982 and 1997 (table 5) (Hochberg et al, 1997). Classification criteria were developed to ensure a consistent case definition of SLE for inclusion in clinical research and randomized controlled trial: they are intended to be applied in patients to whom a clinical diagnosis of SLE was previously established. Nonetheless, these criteria are often used to assist diagnosis despite there are some caveats about their use for this purpose. The ACR criteria were developed and validated in patients with longstanding established disease and may exclude patients with early or limited disease. Some systems are over-represented, such as the mucocutaneous manifestations (photosensitivity, malar rash, discoid lesions and oral ulcers) (Bertsias et al, 2013). All features contribute equally without any weight based upon sensitivity and specificity.

Table 5 The revised ACR and the SLICC classification criteria for SLE

Criteria	ACR criteria (1997 update) (Tan et al, 1982; Hochberg, 1997)	SLICC criteria (2012) (Petri et al, 2012a*)
Skin	<ol style="list-style-type: none"> Malar rash (fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds) Discoid rash (erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring occur in older lesions) Photosensitivity (skin rash as a result of unusual reaction to sunlight, by patient history or physician observation) 	<ol style="list-style-type: none"> Acute cutaneous lupus (lupus malar rash, do not count if malar discoid ; bullous lupus ; toxic epidermal necrolysis variant of SLE ; maculopapular lupus rash ; photosensitive lupus rash), or subacute cutaneous lupus (non-indurated psoriasiform and/or annular polycyclic lesions that resolve without scarring) Chronic cutaneous lupus (classic discoid rash: localised or generalised ; hypertrophic verrucous lupus ; lupus panniculitis profundus ; mucosal lupus ; lupus

		erythematosus tumidus ; chilblain lupus ; discoid lupus/lichen planus overlap) 3. Non-scarring alopecia
Ulcers	4. Oral or nasopharyngeal ulceration	4. Oral or nasal ulcers
Synovitis	5. Non-erosive arthritis (involving ≥ 2 peripheral joints, characterised by tenderness, swelling or effusion)	5. Inflammatory synovitis (in ≥ 2 joints: a. Characterised by swelling or effusion, or b. Tenderness and ≥ 30 min of morning stiffness)
Serositis	6. Any of: a. Pleuritis (convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion) ; b. Pericarditis (documented by ECG or rub or evidence of pericardial effusion)	6. Any of: a. Typical pleurisy (lasting >1 day, or pleural effusions, or pleural rub) b. Typical pericardial pain (pain with recumbency improved by sitting forward, for >1 day), or pericardial effusion, or pericardial rub or pericarditis by electrocardiography
Renal disorder	7. Any of: a. Persistent proteinuria >0.5 g/day, or $>3+$ if measurement is not performed ; b. Cellular casts : red cell, haemoglobin, granular tubular or mixed	7. Any of: a. Urine protein/creatinine (or 24 h urine protein) representing ≥ 500 mg of protein/24 h, or b. Red blood cell casts
Neurological disorder	8. Any of: a. Seizures ; b. Psychosis (in the absence of offending drugs or known metabolic derangements)	8. Any of: a. Seizures ; b. Psychosis ; c. Mononeuritis multiplex ; d. Myelitis ; e. Peripheral or cranial neuropathy ; f. Cerebritis (acute confusional state)
Haematological disorder	9. Any of: a. Haemolytic anaemia (with reticulocytosis) ; b. Lymphopenia ($<1500/\text{mm}^3$); c. Thrombocytopenia ($<100.000/\text{mm}^3$)	9. Haemolytic anaemia 10. Leukopenia ($<4000/\text{mm}^3$), or 11. lymphopenia ($<1000/\text{mm}^3$) at least once 11. Thrombocytopenia ($<100\ 000/\text{mm}^3$) at least once
Immunological disorder	10. Any of: a. Anti-DNA antibody to native DNA in abnormal titer; b. Anti-Sm (presence of antibody to Sm nuclear antigen) ; c. Positive finding of antiphospholipid antibodies (based on: 1. an abnormal serum concentration of IgG or IgM anticardiolipin antibodies ; 2. a positive test result for SLE anticoagulant ; or 3. a false-positive serological test for syphilis, known to be positive for ≥ 6 months and confirmed by negative <i>Treponema pallidum</i> immobilisation or fluorescent treponemal antibody absorption test)	12. Anti-dsDNA above laboratory reference range (except ELISA: twice above laboratory reference range) 13. Anti-Sm 14. Antiphospholipid antibody positivity: lupus anticoagulant, false-positive test for syphilis (rapid plasma reagin), anticardiolipin (medium or high titer IgG, IgM, or IgA), or anti- $\beta 2$ glycoprotein 1 (positive IgG, IgM, IgA) 15. Low complement : low C3, or low C4, or low CH50 16. Direct Coombs' test (in the absence of haemolytic anaemia)

Antinuclear antibody	11. Abnormal titre of ANA (by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with drug-induced lupus)	17. ANA (above laboratory reference range)
Classification of SLE	At least 4 out of 11 criteria	Either biopsy-proven lupus nephritis in the presence of ANA OR anti-dsDNA as a 'stand-alone' criterion, OR four criteria with at least one of the clinical and one of the immunological/ANA criteria

ACR, American College of Rheumatology; ANA, antinuclear antibody; SLE, systemic lupus erythematosus; SLICC, Systemic Lupus International Collaborating Clinics.

The Systemic Lupus International Collaborating Clinics (SLICC) group undertook a revision of the ACR criteria using 'real-case patient scenarios' (table 5) (Petri et al, 2012a*). A patient is classified as having SLE if: (a) has biopsy-proven lupus nephritis (LN) with positive antinuclear antibody (ANA) or anti-dsDNA as a stand-alone criterion; or, (b) the patient satisfies four of the revised criteria, including at least one of the clinical and one of the immunological/ANA criteria. This classification rule had better sensitivity than the ACR criteria (97% versus 83%), at the cost of lesser specificity (96% versus 84%), but, importantly, resulted in fewer misclassifications in regard to the "gold-standard" expert clinical diagnosis.

Main differences introduced by the SLICC criteria include: one cutaneous criterion includes a larger number of acute and subacute manifestations as they largely overlap; the scope of neurologic manifestations was also expanded but still counted in one criterion and low complement was integrated in the immunologic criteria, reflecting its importance to disease pathogenesis. Another important aspect is that applying the SLICC criteria, biopsy-proven lupus nephritis is sufficient for classification of SLE in the presence of ANA or anti-dsDNA antibodies. One study with the GLADEL South-American registry found that the SLICC criteria may delay (or miss) the classification of SLE in some patients because of combining malar rash with photosensitivity (Pons-Estel et al, 2014). On the contrary, a multicentre European study found that in SLE patients with earlier disease (≤ 5 years since onset) the sensitivity of the SLICC criteria was higher compared to the ACR (93.2% versus 85.6%, respectively), because of the increased scope of clinical and immunologic features included (Inês et al, 2015*).

7 Monitoring SLE patients

Recommendations for the initial assessment and frequency of monitoring for patients with SLE are shown in table 6 (Tunnicliffe et al, 2015).

Table 6 Recommended initial assessment and monitoring of systemic lupus erythematosus**History: review of all systems**

Evaluate all presenting symptoms, intercurrents, including, but not limited to:

- Joint pain/swelling, Raynaud's phenomenon
- Photosensitivity, rash, hair loss,
- Shortness of breath, pleuritic chest pain
- General symptoms (depression, fatigue, fever, weight change)
- Comorbidities

Physical examination

Evaluate all features as suggested by history/symptoms, including, but not limited to:

- Mucocutaneous lesions
- Arthritis and other musculoskeletal features
- Lymphadenopathy, splenomegaly
- Cardiovascular and respiratory system

Imaging: laboratory data

- Haematology with complete blood count*
- Blood chemistry*
- Coagulation tests (PT/PTT), antiphospholipid antibodies
- Urine analysis (with protein/creatinine ratio)*
- Serology (ANA, ENA, anti-dsDNA*, complement C3, C4*)
- Chest X-ray examination
- ECG
- Other tests as suggested by history/symptoms

Disease activity index

At each visit or at least when considering major changes in treatment

Treatment side effects and compliance

At each visit

Damage index (SLICC)

Every 1 year

**Every 3–6 months, if stable. Every 1–3 months in patients with active disease.*

ANA, antinuclear antibody; ENA, extractable nuclear antigen; PT, prothrombin time; PTT, partial thromboplastin time; SLICC, Systemic Lupus International Collaborating Clinics.

7.1 Monitoring disease activity

Disease activity needs to be distinguished from damage as this has important implications for the appropriate treatment and the long-term prognosis. Several validated activity indices are used in the evaluation of patients with SLE (Urowitz and Gladman, 1998; Rao and Gordon, 2014*; Romero-Diaz et al, 2011*) including the European Consensus Lupus Activity Measure (ECLAM), the British Isles Lupus Assessment Group Index (BILAG), the Lupus Activity Index (LAI), the National Institutes of Health SLE Index Score (SIS), the Systemic Lupus Activity Measure (SLAM) and the SLE Disease Activity Index (SLEDAI) (SLEDAI-2K or SELENA-SLEDAI versions). SLEDAI is the most widely used (table 7). A crucial issue with the application of any of these indexes is that only

features attributable to active SLE should be scored. The use of at least one of these indices for monitoring disease activity is highly recommended (Vitali et al, 1999; Fanouriakis and Bertsias, 2015). Its use helps the clinician to quantify the disease activity in an objective and standardized way at each visit and in longitudinal follow-up to appreciate changes and response to treatment. However, the clinician should be well aware of the limitations of these instruments and use them as an aid and not a substitute for clinical judgment. These indices were shown to be predictors of damage and mortality, and reflect changes in disease activity (Lopez et al, 2012). For clinical trials, composite endpoints and responder indexes may be more useful (Navarra et al, 2011). Practical issues on monitoring disease activity are explored in the interactive clinical cases of this module.

Table 7 The Systemic Lupus Erythematosus Disease Activity Index-2K (SLEDAI-2K)

Weight	Descriptor	Definition
8	Seizure	Recent onset, exclude metabolic, infectious or drug causes
8	Psychosis	Altered ability to function in normal activity due to severe disturbance in the perception of reality. Includes hallucinations, incoherence, marked loose associations, impoverished thought content, marked illogical thinking, bizarre, disorganised or catatonic behaviour. Exclude uraemia and drug causes
8	Organic brain syndrome	Altered mental function with impaired orientation, memory, or other intellectual function, with rapid onset and fluctuating clinical features, inability to sustain attention to environment, plus at least two of the following: perceptual disturbance, incoherent speech, insomnia or daytime drowsiness, or increased or decreased psychomotor activity. Exclude metabolic, infectious or drug causes
8	Visual disturbance	Retinal changes of SLE. Include cytoid bodies, retinal haemorrhages, serous exudate or haemorrhages in the choroid, or optic neuritis. Exclude hypertension, infection, or drug causes
8	Cranial nerve disorder	New onset of sensory or motor neuropathy involving cranial nerves
8	Lupus headache	Severe, persistent headache; may be migrainous, but must be non-responsive to narcotic analgesia
8	Cerebrovascular accident	New onset of cerebrovascular accident(s). Exclude arteriosclerosis
8	Vasculitis	Ulceration, gangrene, tender finger nodules, periungual infarction, splinter haemorrhages or biopsy or angiogram proof of vasculitis
4	Arthritis	>2 Joints with pain and signs of inflammation (i.e., tenderness, swelling or effusion)
4	Myositis	Proximal muscle aching/weakness, associated with raised creatine phosphokinase/aldolase or electromyogram changes or a biopsy showing myositis
4	Urinary casts	Haem-granular or red blood cell casts
4	Haematuria	>5 Red blood cells/high-power field. Exclude stone, infection or other cause

4	Proteinuria	>0.5 g/24 h
4	Pyuria	>5 White blood cells/high-power field. Exclude infection
2	Rash	Inflammatory type rash
2	Alopecia	Abnormal, patchy or diffuse loss of hair
2	Mucosal ulcers	Oral or nasal ulcerations
2	Pleurisy	Pleuritic chest pain with pleural rub or effusion, or pleural thickening
2	Pericarditis	Pericardial pain with at least one of the following: rub, effusion, or electrocardiogram or echocardiogram confirmation
2	Low complement	Decrease in CH50, C3, or C4 below the lower limit of normal for testing laboratory
2	Increased DNA binding	Increased DNA binding by Farr assay above normal range for testing laboratory
1	Fever	>38°C. Exclude infectious cause
1	Thrombocytopenia	<100 000 platelets $\times 10^9/L$, exclude drug causes
1	Leukopenia	<3000 white blood cells $\times 10^9/L$, exclude drug causes

For an item to be scored the indicated weight, the manifestation must have been present in the past 10 days (original SLEDAI-2k) or 30 days (SLEDAI-2k 30- day version) at attributed to active lupus disease activity.

7.2 Monitoring damage and comorbidities

The SLICC/ACR Damage Index (SDI) is a validated instrument designed to ascertain damage in SLE patients (table 8) (Chambers et al, 2009; Nossent et al, 2010). SLE-related damage may be due to the disease itself or to drug treatment, particularly glucocorticoids (Petri et al, 2012b; Yee et al, 2015*). Of note, the SDI scores only irreversible damage starting after the SLE diagnosis, and regardless of its attribution to SLE-related or non-related causes. SDI records damage in 12 organs or domains; furthermore, to ensure that the damage recorded is irreversible, most features are required to be present for at least 6 months before being scored. The scoring in SDI is categorical, however a weight >1 is attributed to some features. Up to 40–50% of patients with SLE develop damage within 5 to 10 years from disease diagnosis. Most frequently affected domains are the musculoskeletal, eyes (cataract), skin (scarring alopecia), cardiovascular, renal and neurological (Urowitz et al, 2012). Organ damage is a strong predictor of further damage accrual and increased patient mortality (Bruce et al, 2015*). However, the SDI does not consider many important comorbidities or any damage starting before the SLE diagnosis, which may significantly influence in an individual patient's quality of life and survival.

Practical issues on monitoring damage are explored in the interactive clinical cases of this module.

Table 8 The SLICC/ACR Damage Index for SLE

Item	Score
Ocular (either eye by clinical assessment)	
Any cataract ever	1
Retinal change or optic atrophy	1
Neuropsychiatric	
Cognitive impairment (eg, memory deficit, difficulty with calculation, poor concentration, difficulty in spoken or written language, impaired performance level) or major psychosis	1
Seizures requiring treatment for 6 months	1
Cerebrovascular accident ever (score 2 if >1)	1, 2
Cranial or peripheral neuropathy (excluding optic)	1
Transverse myelitis	1
Renal	
Estimated or measured glomerular filtration rate <50%	1
Proteinuria >3.5 g/24 h	1
or End-stage renal disease (regardless of dialysis or transplantation)	3
Pulmonary	
Pulmonary hypertension (right ventricular prominence, or loud P2)	1
Pulmonary fibrosis (physical and radiographical)	1
Shrinking lung (radiograph)	1
Pleural fibrosis (radiograph)	1
Pulmonary infarction (radiograph)	1
Cardiovascular	
Angina or coronary artery bypass	1
Myocardial infarction ever (score 2 if >1)	1, 2
Cardiomyopathy (ventricular dysfunction)	1
Valvular disease (diastolic murmur, or systolic murmur >3/6)	1
Pericarditis for 6 months or pericardiectomy	1
Peripheral vascular	
Claudication for 6 months	1
Minor tissue loss (pulp space)	1
Significant tissue loss ever (eg, loss of digit or limb) (score 2 if >1 site)	1, 2
Venous thrombosis with swelling, ulceration or venous stasis	1
Gastrointestinal	
Infarction or resection of bowel below duodenum, spleen, liver or gallbladder ever, for any cause (score 2 if >1 site)	1, 2
Mesenteric insufficiency	1
Chronic peritonitis	1
Stricture or upper gastrointestinal tract surgery ever	1
Chronic pancreatitis	1, 2
Musculoskeletal	
Muscle atrophy or weakness	1
Deforming or erosive arthritis (including reversible deformities, excluding avascular necrosis)	1
Osteoporosis with fracture or vertebral collapse (excluding avascular necrosis)	1
Avascular necrosis (score 2 if >1)	1, 2

Osteomyelitis	1
Tendon rupture	1
Skin	
Scarring chronic alopecia	1
Extensive scarring of panniculum other than sculp and pulp space	1
Skin ulceration (excluding thrombosis for >6 months)	1
Premature gonadal failure	1
Diabetes (regardless of treatment)	1
Malignancy (exclude dysplasia) (score 2 if >1 site)	1

SLICC, Systemic Lupus International Collaborating Clinics.

7.3. Assessment in special situations

7.3.1 Women's health issues and pregnancy

Most patients with SLE are women and the diagnosis is generally established in childbearing age. These patients present special needs regarding education, assessment and management on reproductive and other women's health issues. Important conditions to consider include pregnancy risks posed by antiphospholipid antibodies, anti-SSA/SSB (Ro/La) antibodies, lupus disease activity and medication adverse effects. Appropriate contraception and family planning are of paramount importance. With adequate management, most SLE patients can expect successful pregnancies. Antiphospholipid syndrome and pregnancy issues are approached in another module. The EULAR recently elaborated recommendations on women's health issues in SLE patients (Andreoli et al, 2017*).

7.3.2 Lupus in childhood and adolescence

About 15–20% of all SLE cases are diagnosed in childhood (Jimenez et al, 2003). Paediatric SLE may differ from adult SLE, in disease expression, physiological, developmental and psychosocial features. Knowledge of paediatric-onset SLE is more limited as compared to adult-onset, regarding epidemiology, long-term outcome and optimal management specificities (Ardoin et al, 2005). Despite that assessment principles applied in the adults are used for paediatric lupus, special needs of these populations should be taken into consideration (Lattanzi et al, 2011).

7.3.3 Elderly age

Later-onset SLE, after 50 years of age, occurs in 10-20% of patients. These tend to present less frequently with lupus nephritis, cutaneous features or cytopenias. However, disease activity and damage are not milder in this subgroup (Lalani et al, 2010). Differential diagnosis in late-onset SLE patients can be challenging, due to low SLE incidence and presentation with clinical features similar to those of more common disorders in this age group. An increasingly more frequent group is constituted by elderly patients with longstanding SLE, with earlier age of onset. In older patients, damage from SLE related and unrelated causes, as well as comorbidities,

have high prevalence and require careful assessment. Attribution of a feature to active SLE versus damage or comorbidities is also challenging: an example is the differential diagnosis of lupus arthritis in hand joints with previous osteoarthritis versus a flare of osteoarthritis.

7.3.4 Drug-induced lupus (DIL)

A variety of drugs have been identified as possible causes of lupus. DIL should be suspected in patients with no diagnosis or history of SLE, who develop a positive ANA and at least one clinical feature of lupus after an appropriate duration of drug exposure, and whose symptoms resolve when the drug is stopped. Clinical features include fever, myalgias, rash, arthritis and serositis. Haematological abnormalities, kidney disease and CNS lupus are uncommon. Anti-histone antibodies are present in >95%, whereas hypocomplementaemia and anti-DNA antibodies are rare, with the exception of disease associated with use of IFN α and anti-tumour necrosis factor therapies.

7.3.5 Emergencies, hospitalization and life-threatening illness

Patients with SLE may visit the emergency room owing to complications related to lupus itself or its treatment, or for unrelated reasons. Risk of incorrect attribution to SLE disease activity of unrelated health problems, as well as failure to diagnosis potentially life-threatening acute lupus manifestations are important challenges in the assessment of these patients in the emergency room. Poor compliance, low education level, infections, and high disease activity or damage are risk factors for hospitalization (Lee et al, 2013).

Life-threatening illness may develop from: (a) exacerbation of pre-existing or new manifestations of SLE; (b) infections; (c) adverse effects of drugs used to treat SLE or other concomitant conditions; (d) malignancy; and (e) acute serious illnesses that are unrelated to SLE (but whose manifestations may be altered by it).

Differential diagnosis of infections and SLE disease activity is challenging, and they can coexist, especially in acutely ill patients treated with high-dose glucocorticoids. The clinical (i.e. fever) and analytical (i.e. acute-phase reactants) features of infections can be masked by moderate to high-dose glucocorticoids.

Vascular acute events (myocardial or cerebrovascular) due to premature atherosclerosis are a frequent cause of morbidity in SLE patients and tend to present at an earlier age as compared to the general population (Bruce et al, 2000; Asanuma et al, 2003; Roman et al, 2003). Most coronary occlusive disease in SLE results from atherosclerosis or thrombosis. Cerebrovascular accidents can be caused by intracranial haemorrhage from ruptured aneurysms, thrombotic events from atherosclerosis or antiphospholipid antibodies, or from cardiac emboli (Futrell and Millikan, 1989; Kitagawa et al, 1990). Spinal cord transverse myelopathy is a devastating acute manifestation of SLE.

Acute abdominal pain in SLE may be secondary to mesenteric arterial thrombosis, ischaemic bowel, ruptured hepatic aneurysms, cholecystitis, perforated rectal ulcer, appendix, caecum or colon and pancreatitis

(McCollum et al, 1979; Kojima et al, 1997). An acute abdomen presentation can be masked by moderate to high glucocorticoids treatment. Patients with active SLE presenting with acute or subacute abdominal pain and high disease activity are more likely to have active mesenteric vasculitis and should be promptly referred for abdominal CT scan.

8 Prognosis

8.1 Predicting disease course and flares

Although treatment of lupus has dramatically improved survival, prolonged and complete remission—defined as 5 years without clinical and laboratory evidence of active disease and receiving no treatment—has remained elusive for many patients. The incidence of flare is estimated to be up to 0.50 flares per patient-year. Moreover, a significant number of patients (10–20% in tertiary referral centres) do not respond adequately to immunosuppressive therapies. Predictors of increased risk of flare include those patients with an earlier age at SLE diagnosis (≤ 25 years), those with previous lupus nephritis, neurologic or vasculitis involvement, high serum levels of anti-dsDNA, low C3, and those requiring treatment with immunosuppressants (Inês et al, 2014*; Petri et al, 2013).

8.2 Morbidity, comorbidities and mortality

The incidence of hospital admissions for patients with SLE is 0.69 admissions per patient-year. Infections, severe lupus disease activity in major organs, coronary artery disease and orthopaedic management of osteonecrosis are prominent reasons for hospitalization.

8.2.1 Infections

Infections account for 20–55% of all deaths in patients with SLE. Susceptibility to infections may be due to underlying immune deregulation and therapeutic factors, particularly high-dose glucocorticoids (GCs) and immunosuppressive drugs. A broad spectrum of infections has been reported in SLE (Navarra and Leynes, 2010). Risk factors are increased clinical and/or serological lupus activity (Jeong et al, 2009; Navarro-Zarza et al, 2010), major organ involvement, especially renal (Goldblatt et al, 2009) and lung involvement (Ruiz-Irastorza et al, 2009), persistent neutropenia ($<1000/\text{mm}^3$) (Dias et al, 2009), hypoalbuminaemia for severe CNS infections (Yang et al, 2007), high dose of glucocorticoids (Ruiz-Irastorza et al, 2009) and previous (within the past 6 months) use of cytotoxic drugs (Bosch et al, 2006; Zhou and Yang, 2009; Navarro-Zarza et al, 2010). Findings that favour the diagnosis of infection include rigors, leucocytosis and/or neutrophilia (especially in the absence of moderate/high dose glucocorticoid therapy), increased number of metamyelocytes on peripheral blood smear and concomitant immunosuppressive therapy. Diagnosis of SLE fever is more likely in the presence of leukopenia (not explained by cytotoxic therapy), normal or only slightly increased C-reactive

protein, low C3/C4 and raised anti-DNA antibodies. While awaiting microbiology results, antimicrobial therapy is recommended (Chen et al, 2008; Feng et al, 2010).

8.2.2 Atherosclerosis

Patients with SLE have an increased risk of developing coronary heart disease compared with age-matched controls. Aggressive treatment of dyslipidaemia (low-density lipoprotein-cholesterol <100 mg/dL, triglycerides <150 mg/dL) is recommended for patients with multiple risk factors, especially those with moderate/severe SLE, and with carotid thickening shown by ultrasound imaging.

8.2.3 Osteoporosis

In SLE patients, uncontrolled disease activity, premature menopause related to use of cyclophosphamide, relative vitamin D deficiency due to avoidance of sun exposure and the use of systemic glucocorticoids, all contribute to reduced bone mineral density and fragility fractures, in addition to those risk factors prevalent in the general population.

8.2.4 Malignancies

Haematological malignancies (particularly non-Hodgkin's lymphoma), lung, liver and thyroid cancer occur more commonly in SLE than in the general population (Tessier-Cloutier et al, 2014). Immunosuppressive therapy and intrinsic SLE-related mechanisms could account for this risk. Non-Hodgkin's lymphoma is associated with SLE (standardised incidence ratio: 4.4–5.7), with the most commonly identified histological subtype being diffuse large B cell lymphoma, which usually runs an aggressive course. Hodgkin's lymphoma is also more common in SLE. The risk for haematological malignancies may increase after exposure to immunosuppressive drugs, particularly in the 5 years after stopping treatment. Cervical dysplasia is increased in women with SLE owing to exposure to cytotoxic agents, particularly cyclophosphamide. Therefore, SLE should be regarded as a risk factor for HPV infection and cervical malignancy. Although the efficacy of HPV vaccine has not been investigated in patients with autoimmune diseases, the EULAR guidelines recommend that HPV vaccination should be considered for women with SLE as for the general population.

8.3 Prognosis of SLE in Europe

The 'Euro-Lupus Cohort' is composed of 1000 patients with SLE followed up prospectively since 1991 (Cervera et al, 1993; Cervera et al, 1999*; Cervera and Khamashta, 2006; Cervera et al, 2006; Cervera et al, 2009). Seventy-six of the 1000 patients (8%) developed the disease before the age of 14. Patients with childhood-onset SLE were more likely to have severe organ involvement, especially nephropathy, at presentation. Other major manifestations, such as neurological involvement, thrombocytopenia and haemolytic anaemia, were also common initial features in the childhood-onset group. However, during the disease evolution, the pattern

was quite similar in patients with childhood-onset disease and adult patients. Ninety patients (9%) developed the disease after the age of 50. Female predominance was not so pronounced in the older-onset group (5:1). The clinical picture in patients with older-onset disease best resembles that of patients with drug-induced SLE, primary Sjögren's syndrome or polymyalgia rheumatica. Typical SLE manifestations, such as malar rash, photosensitivity, arthritis or nephropathy, were less common than in younger patients, whereas sicca syndrome was common. A higher prevalence of serositis was found in male patients at presentation. In contrast, arthritis occurred less commonly in men. During disease evolution, a lower prevalence of arthritis was found in the male subjects. The prevalence of nephropathy, neurological involvement, thrombocytopenia, vasculitis and serositis was similar in both groups. No significant immunological differences were found between men and women. The frequencies of the main lupus manifestations during the initial 10 years of the 'Euro-Lupus Cohort' are slightly lower than those reported in large series from America and Asia. There was a lower frequency of most SLE manifestations during the last 5 years (1995–2000) (Cervera et al, 1999*), compared with the cumulative clinical manifestations during the initial 5 years of the study (1990–1995). In the Euro-Lupus Cohort, 10 years after entry into the study, survival was 92% (Cervera et al, 2001). The slightly higher survival in this cohort than in the American series may be due to the predominance of Caucasian patients (97%). There was a similar percentage of patients with active SLE (27%), thromboses (27%) and infections (25%) as the main causes of death. However, when the causes of death during the initial 5 years were compared with those during the ensuing 5 years, active SLE and infections (29%, each) appeared to be the most common causes during the initial 5 years, while thromboses (26%) became the most common cause of death during the last 5 years.

9 Patient-reported outcomes and socioeconomic impact

There are a number of patient-reported outcomes (PRO) that can be assessed with validated indexes in SLE patients. These include indexes for screening possible disease activity, organ damage, health-related quality of life (HRQoL), fatigue and work productivity (Holloway et al, 2014*).

The Systemic Lupus Activity Questionnaire (SLAQ) was developed for surveying disease activity in large groups of SLE patients in population studies and can be self-administered outside the clinical setting (Karlson et al, 2003; Yazdany et al, 2008; Chehab et al, 2015). For the same setting, organ damage can be estimated with the Brief Index of Lupus Damage (BILD) (Yazdany et al, 2011; Chehab et al, 2013) or the Lupus Damage Index Questionnaire (LDIQ) (Costenbader et al, 2010).

The self-perception of quality of life is significantly lower in SLE patients compared to the general population (Stoll et al, 1997). Impairment of HRQoL may result from a variety of intermingled factors, including disease activity, organ damage, comorbidities (such as fibromyalgia), adverse effects from medication and socioeconomic factors. This is an outcome of central importance from the patient's perspective and should be

taken in consideration in the clinical setting for facilitating shared decision on management goals (Mahieu et al, 2016). HRQoL measures are included in clinical trials and observational studies of SLE patients (Annapureddy et al, 2016). Both generic instruments, such as the Short form 36 (SF-36) (Stoll et al, 1997), and SLE-specific HRQoL tools are used. The lupus-specific tools include the Lupus Patient Reported Outcome (LupusPRO) (Jolly et al, 2012), LupusQoL (McElhone et al, 2007) and SLEQOL (Leong et al, 2005).

Compromise of HRQoL is an important component of the global burden of SLE. This intangible cost adds to high direct (healthcare) and indirect costs owing to loss of economic productivity associated with SLE (Carter et al, 2016*). Expensive new drugs are in development aiming to fulfil unmet needs for SLE treatment. However, outcomes of the SLE population are recognized to be greatly impacted by failure to extend benefits of current evidence-based management recommendations to many patients. Unfavourable disease outcomes are associated with poverty, low educational status, lack of access to appropriate healthcare, poor social support and treatment compliance issues (Alarcón et al, 2006; Carter et al, 2016*).

10 Evidence-based recommendations for the management of SLE

The EULAR has developed recommendations covering the most important aspects of the management of SLE (Bertsias et al, 2008*; Bertsias et al, 2010a*; Bertsias et al, 2012*; Andreoli et al, 2017*). These can be freely accessed at the EULAR site. Management and treatment of SLE is discussed in the next module.

SUMMARY POINTS

- Systemic lupus erythematosus (SLE) is a chronic autoimmune disorder characterised by a broad spectrum of multisystemic manifestations.
- The pathogenesis of SLE is complex and includes genetic, hormonal and environmental factors.
- Peak onset is between the ages of 16 and 55. Women are affected up to twelve times more frequently than men.
- Age at onset, gender, ethnicity and immunological features influence the prevalence of clinical manifestations and disease evolution.
- Classification criteria were developed to ensure a consistent case definition of SLE for inclusion in clinical research and trials.
- There are no diagnostic criteria or pathognomonic features for the disease. The diagnosis is based on clinical and analytical features, while considering alternative causes for the clinical picture.
- Several validated activity indices are used to monitor disease activity in SLE patients. The SLICC/ACR criteria is a validated instrument to ascertain damage.
- There were significant improvements in long-term survival but patients with SLE still have higher morbidity and mortality than the general population.
- Factors contributing to mortality include high disease activity, damage accrual and low socioeconomic status. Infections, cardiovascular disease, malignancy and disease activity are major causes of death.

IN-DEPTH DISCUSSION I

Neuropsychiatric manifestations in SLE

Introduction

Neuropsychiatric (NP) manifestations in SLE include a wide range of neurologic and psychiatric features. Despite advances in the understanding of the pathogenic and clinical aspects of SLE, neuropsychiatric features remain a diagnostic and therapeutic challenge (Govoni *et al.*, 2016). Major difficulties include the selection of adequate diagnostic workup, correct attribution of neuropsychiatric manifestations to SLE or other causes and the appropriate management in view of the paucity of trial data (Hanly, 2014).

Epidemiology

The reported prevalence of NP in SLE ranges from 12% to 95% (Bertsias and Boumpas, 2010). This wide range owes to differences in research methodology, cohort characteristics, diagnostic workup and attribution of neuropsychiatric events to SLE. A key concept is that most of NP manifestations in SLE patients are not attributable to lupus disease activity (Hanly *et al.*, 2010). The American College of Rheumatology (ACR) Ad Hoc Committee on Neuropsychiatric Lupus has proposed a nomenclature for 19 NP syndromes known to occur in SLE patients (The American College of Rheumatology nomenclature and case definitions for neuropsychiatric lupus syndromes, 1999). These standardized NP definitions are useful both in clinical practice and in research but do not imply any assumption of attribution to SLE. Mild NP syndromes such as headache or mood disorders are the most common: in a prospective international inception cohort study, the prevalence of headache was 58% after 10 years of follow-up (Hanly *et al.*, 2013); mood disorders occurred in 13% of the patients (Hanly *et al.*, 2015). Most of these NP syndromes were not associated with lupus disease activity and attributed to non-SLE causes. (Hanly *et al.*, 2013; Hanly *et al.*, 2015). Clinically severe NP involvement attributable to SLE is rare: in a prospective study of 360 patients from a Greek cohort over 3 years, the frequency of major central nervous system (CNS) events attributed to lupus was 4.3% (Kampylafka *et al.*, 2013). Due to the complex and interrelated aetiopathogenic mechanisms, NP events may occur in SLE patients at any time of the disease course.

Risk Factors

SLE-specific Risk Factors

Persistently positive, moderate-to-high titers of antiphospholipid antibodies (aPL) were associated to at least a fivefold increased risk of major NP events in SLE patients (Bertsias *et al.*, 2010). Positive aPL were associated with cerebrovascular disease (CVD), seizures, myelopathy, chorea and moderate to severe cognitive dysfunction (Sanna *et al.*, 2003). In a multicentre retrospective cohort study of 959 SLE patients, aPL emerged as the strongest risk factor for focal NP syndromes (Govoni *et al.*, 2012).

Previous or concurrent major NP syndromes, particularly stroke and seizures, were predictive of future NP events in several studies (Bujan *et al.*, 2003). Other consistent risk factor for NP manifestations is increased SLE activity and damage, with a robust association to seizure disorders and severe cognitive dysfunction. Indeed, increased systemic SLE disease activity was associated with concurrent NP events attributed to SLE, particularly for diffuse NP and CNS NP events (Morrison *et al.*, 2014). It is important to emphasise that although rare, the absence of overt SLE activity does not exclude that NP manifestations due to SLE. However, it implies a careful assessment of all the mimics (Rodrigues *et al.*, 2017).

SLE non-specific Risk Factors

Non-SLE related factors such as older age, hypertension, dyslipidaemia and other traditional risk factors were related to cognitive dysfunction, depression and CVD (Govoni *et al.*, 2016). Fibromyalgia and social impairment are increased in SLE patients and associated to depression, anxiety and mild memory and cognitive problems. Large studies correlated these factors to SLE duration and to the chronic burden of the disease rather than to SLE disease activity (Torrente-Segarra *et al.*, 2016). Other frequent risk factors in SLE patients, such as infection, metabolic disturbances and medication effects, especially glucocorticoids (GC), were associated to diverse NP syndromes (Bhangle *et al.*, 2013).

Pathogenesis

NP syndromes in SLE patients can result from lupus-specific mechanisms such as vascular abnormalities, autoantibodies and inflammatory mediators. These may interact in complex pathogenic mechanisms.

Vascular abnormalities

A vascular occlusive process is the most commonly reported. SLE-associated vasculopathy enhanced by endothelial activation and injury mediated by aPL is a plausible mechanism. The activation of the clotting cascade with hypercoagulable state increases the susceptibility to thrombotic phenomena both in large and small vessels (Belmont *et al.*, 1996). A true inflammatory process characterised by vasculitis with a transmural infiltrate and fibrinoid necrosis is rare (Rodrigues *et al.*, 2017).

Autoantibodies

A potential pathogenic role was proposed for anti-neuronal and anti-glutamate-receptor antibodies. The first was found to be elevated in the cerebrospinal fluid (CSF) of SLE patients with NP manifestations (Kang *et al.*, 2008). The latter was related in experimental studies to hippocampal apoptosis and cognitive dysfunction. Anti-ribosomal-P antibodies are found in up to 25% of patients with SLE. Their association with NP syndromes such as psychosis and depression were reported in some studies but remains controversial (Hanly *et al.*, 2011). In animal models, enhanced permeability of the blood-brain barrier is critical for the access of antibodies to

the cerebral parenchyma (Kowal *et al.*, 2004). Both SLE factors (immune complex or cytokines) and non-SLE factors (smoking or hypertension) may have a combined role on the barrier dysfunction that is a key factor for the pathogenesis of NP syndromes.

Inflammatory mediators

In experimental studies, neuronal and glial cells produce several cytokines in response to the presence of autoantibodies within the intrathecal space. Proinflammatory cytokines that may contribute to pathogenesis of NP manifestations include interferon- α , IL-2, IL-6, IL-8 and IL-10 (Trysberg *et al.*, 2000).

Classification of Neuropsychiatric manifestations in SLE

In the ACR nomenclature for neuropsychiatric syndromes in SLE, these are divided in two groups, depending whether there is central or peripheral nervous system involvement (Box 1). For each of these syndromes, a complete case definition, diagnostic criteria, and methods for ascertainment are proposed for use in clinical practice and research studies. This case definition provided a standardized description for each clinical NP syndrome. Conditions that act as confounders were identified for either exclusion (infection, neoplasia, nervous system primary disease) or recognition as association (hypertension, smoking, diabetes, GC), acknowledging that in some cases a definite attribution is not possible. The nomenclature also intends to expand the neurologic criteria (seizures, psychosis) included in the 1997 ACR classification for SLE. In 2012, the Systemic Lupus International Collaborating Clinics (SLICC) further included mononeuritis multiplex, myelitis, peripheral or cranial neuropathy and acute confusional state in the neurological criteria for SLE classification (Petri *et al.*, 2012). Both ACR and SLICC classification criteria require a confirmed attribution of the NP syndromes to SLE.

Although the ACR classification for NP syndromes standardizes reporting, its use does not replace clinical judgement, since its purpose is not diagnosis. Any of the ACR NP clinical syndromes in SLE patients can be directly caused by SLE or derived from other causes. Furthermore, a few NP syndromes observed in SLE were not included, such as neuromyelitis optica or posterior reversible encephalopathy syndrome (Barber *et al.*, 2011).

Box 1 Neuropsychiatric syndromes in systemic lupus erythematosus.**Central nervous system**

- Aseptic meningitis
- Cerebrovascular disease
- Demyelinating syndrome
- Headache (including migraine and benign intracranial hypertension)
- Movement disorder (chorea)
- Myelopathy
- Seizure disorder
- Acute confusional state
- Anxiety disorder
- Cognitive dysfunction
- Mood disorder
- Psychosis

Peripheral nervous system

- Acute inflammatory demyelinating polyradiculoneuropathy (Guillain–Barré syndrome)
- Autonomic disorder
- Mononeuropathy, single/multiplex
- Myasthenia gravis
- Neuropathy, cranial
- Plexopathy
- Polyneuropathy

jreynolds@rheumatology.org.

Diagnosis

The initial evaluation of patients with SLE presenting NP manifestations should aim to exclude the most important mimics before concluding for SLE-mediated CNS dysfunction (Figure 1). The differential diagnosis includes infection, neoplasia, metabolic disturbances, cardiovascular events, drug abuse and medication side effects. A complete medical history and physical examination focusing on past or recent signs of these conditions should be methodically performed.

Glucocorticoids assessment is also an important issue. Association with NP manifestations was reported considering different views: active disease with NP manifestations requiring glucocorticoids for its treatment or glucocorticoids side-effects. Regarding the side-effects, GC are associated with atherosclerosis in SLE, a

frequent mechanism for stroke and other NP syndromes (Doria *et al.*, 2003). Other well recognized side-effect are psychological and behavioural disorders. GC were linked with psychosis, cognitive dysfunction and other NP features. A GC dose-dependent effect was observed in most of these cases (Bhangle *et al.*, 2013)

Depending on the NP manifestations, the diagnostic workup might include biochemical and serological tests, echocardiography and ecodoppler (to exclude cardioembolic disease), lumbar puncture and CSF analysis (to exclude infectious, bleeding or malignant process), electroencephalography (to diagnose seizure disorder) and neuroimaging (to assess brain structure and function) (Table 1).

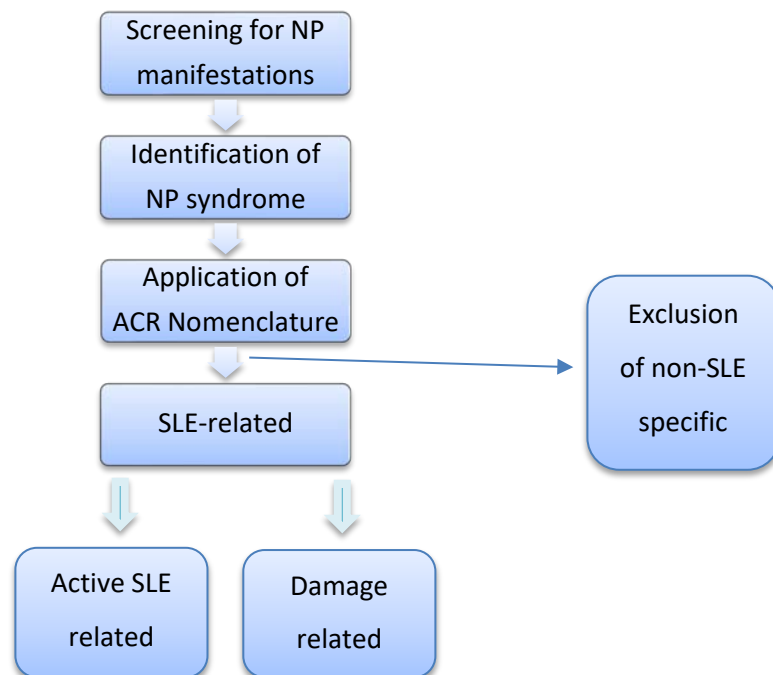

Figure 1 Management of NP manifestations in SLE.

Of all the autoantibodies and serum biomarkers tested, aPL have the greatest diagnostic utility in NP syndromes, especially in patients with focal symptoms or cognitive decline. The association between NP manifestations and other autoantibodies is less clear and careful interpretation should be made combining clinical and imaging data.

Lumbar puncture for CSF analysis is important to exclude non-SLE causes as infection, SNC bleeding or malignancy. The presence of high-risk features as severe or explosive headache onset, fever or concomitant infection, focal neurological signs, decreased level of consciousness, meningismus, overt SLE activity, aPL or antiphospholipid syndrome, use of immunosuppressants or anticoagulants support this diagnostic approach (Bertsias and Boumpas, 2010). Intrinsic immunological defects in SLE, especially in CD4 cells, may predispose SLE patients to opportunistic fungal infections, even without administration of immunosuppressive agents (Hung *et al.*, 2005). Therefore, bacterial (*Listeria monocytogenes*, *Staphylococcus aureus*, *Klebsiella*

pneumonia, Mycobacterium tuberculosis), opportunistic fungal infection (*Cryptococcus neoformans, Aspergillus fumigatus*), viral and parasitic infections need to be considered for the CSF analysis (Yang *et al.*, 2007).

MRI is the current gold standard for cerebral and spinal NP imaging (Bertsias *et al.*, 2010). It is a sensitive method to detect NP typical lesions and to exclude other causes (neoplasia, infection). The most specific pathological pattern in MRI are punctuate, T2-hyperintense lesions in the subcortical and periventricular white matter. However, these lesions are also found in SLE patients without neuropsychiatric manifestations (specificity 60–82%) (Sibbitt *et al.*, 2003). In cases with normal MRI or dissociation between MRI findings and clinical symptoms, quantitative MRI or radionuclide brain scanning may be considered.

Table 1 Clinical reporting, diagnosis and management of NP manifestations.

Clinical reporting		
Demographic	Age, Sex, Ethnicity	
	Highest schooling completed	
SLE Descriptors	Duration	
	Classification Criteria for SLE	
	Basic Laboratory Data	
	Current medications	
	Disease Activity and Damage	
NP Descriptors	Duration	
	Chronology (episodic, remittent, sustained, progressive)	
	Severity (mild, moderate, severe)	
	Isolated or with systemic SLE activity	
	Initial and final diagnosis or diagnoses	
Screening		
Complete Blood Count		
Serum biochemical test	Glycaemia, Uraemia, Na ⁺ , Ca ²⁺ , uraemia, vitamin deficiencies (B12), thyroid function tests	
Autoantibodies	aPL	
Cardiovascular Risk Factors	Dyslipidaemia, Hypertension, Cigarette smoking	
Exposures	Anticholinergics, Sedatives, Glucocorticoids, Drug abuse	
Investigations		
Lumbar Puncture	Infection	CSF biochemical analysis and culture
	Neoplasia	

Electroencephalography	Seizure Disorder	
Electrocardiography	Cerebrovascular Disease	Identification of rhythm and structural abnormalities.
Echocardiography		
Carotid Ecodoppler		Detection of atherosclerotic lesions.
Neuropsychological Tests	Cognitive Dysfunction	Diagnosis and Monitoring
Neuroimaging	Focal NPSLE	MRI
	Diffuse NPSLE with high-risk features after exclusion of non-SLE causes	(T1/T2-weighted, FLAIR, DWI, gadolinium-enhanced T1- sequences)
	Antiphospholipid Syndrome	
Management		
Symptomatic	Mood Disorder	Antidepressant
	Seizure	Anticonvulsant
	Psychosis	Antipsychotic
Immunosuppression	Immune or inflammatory aetiology	Glucocorticoids CYC, MMF, AZA Rituximab, IVIG
Anticoagulation	Vascular injury mediated by aPL	Acetylsalicylic acid Heparin Warfarin

Management

The identification and treatment of triggering or aggravating factors such as cardiovascular disorder, infection, metabolic abnormalities and drug adverse effects (GC and others) is important in all patients. Symptomatic therapy with anticonvulsants (seizure disorder), antidepressants (mood disorders) or antipsychotics (psychosis) should be considered when appropriate (Bertsias *et al.*, 2010). Therapy targeting immune or inflammatory activity is considered after exclusion of non-SLE related causes (Table 1). The selection of therapy upon the predominance of an inflammatory or thrombotic process is fundamental. The only trial of immunosuppressive therapy in NP syndromes in SLE found a significantly better response to combination therapy with intravenous cyclophosphamide than with intravenous methylprednisone alone (Barile-Fabris *et al.*, 2005). There is less evidence for efficacy of azathioprine (AZA) and mycophenolate mofetil (MMF). In some refractory NP syndromes, use of plasma exchange, intravenous immunoglobulin (IVIG) and rituximab (RTX) was reported with varying rates of success (Tokunaga *et al.*, 2007; Camara *et al.*, 2014; Kronbichler *et al.*, 2016). Antiplatelet therapy with or without anticoagulation is recommended when manifestations are related to aPL. Cohort studies suggest a role for antiplatelet agents in the primary prevention of aPL-associated

thrombotic CVD (Tektonidou *et al.*, 2009). Intensive treatment with anticoagulation may be considered for secondary prophylaxis of CVD. In the absence of controlled trials to guide the type, intensity and duration of anticoagulation a similar approach may be inferred from studies in patients with antiphospholipid syndrome (Pengo *et al.*, 2012).

Prognosis

Regardless of attribution, NP manifestations result in decreased quality of life, work disability and increased unemployment (Hanly *et al.*, 2010). The importance of NP involvement on damage accrual in patients with SLE is also reflected in the inclusion of five of the NP syndromes in the SLICC/ACR Damage Index for SLE (Gladman *et al.*, 1996).

Conclusion

NP involvement in SLE is associated with significant morbidity and poor functional outcomes. The diagnosis should rely in a careful clinical assessment and selection of appropriate workup. A complete and standardized characterization and correct attribution to SLE or non-SLE causes represent a crucial point in the effective management of NP manifestations. Further research on biomarkers and neuroimaging may provide better definition of pathogenic mechanisms, diagnostic and treatment strategy, and prognosis.

Systemic lupus erythematosus: pathogenesis and clinical features

Marília Rodrigues, Luís Sousa Inês and Caroline Gordon

Previous versions were coauthored by Sofia Tosounidou, George Bertsias, Caroline Gordon, Dimitros T. Boumpas, Ricard Cervera, Gerard Espinosa, David D'Cruz

IN-DEPTH DISCUSSION II

Shrinking lung syndrome

Introduction

Pleuropulmonary involvement may occur in about 60% of patients with SLE (Orens *et al* 1994). Subclinical involvement occurs even more frequently, with autopsy series reporting a prevalence of up to 93% (Ropes *et al* 1976). SLE may affect all the components of the respiratory system, including airways, lung parenchyma, pulmonary vasculature, pleura and respiratory muscles (Table 1). Pleuritis, with or without pleural effusion is by far the commonest pleuropulmonary manifestation of SLE. A less common but more serious entity is the shrinking lung syndrome (SLS) and this in-depth discussion reviews the clinical features, pathogenesis, investigations, management and outcome of SLS.

SLS was first reported by Hoffbrand *et al* in 1965 who described lupus patients with unexplained dyspnoea, small lung volumes, elevation of the diaphragm, and restrictive physiology. The overall prevalence of SLS in a large multi-ethnic cohort of lupus patients was 0.6%. Higher prevalence (6%) was reported among SLE patients with refractory disease (Bertoli *et al* 2007, Traynor *et al* 2005). SLS was also found in other rheumatic diseases including systemic sclerosis, rheumatoid arthritis and undifferentiated connective tissue disorder. SLS may complicate SLE at any stage with the mean time of SLS onset estimated at 4.3 years after diagnosis of lupus; rarely SLS can be the first manifestation of SLE.

Table 1: Respiratory involvement in SLE

a. Parenchymal involvement	I. Acute lupus pneumonitis
	II. Chronic interstitial lung disease
b. Pleural involvement	Pleurisy with or without effusion and fibrosis
c. Vascular involvement	<i>Non-thromboembolic disease</i>
	I. Diffuse alveolar haemorrhage
	II. Pulmonary arterial hypertension
	III. Acute reversible hypoxaemia
	<i>Thromboembolic disease</i>
d. Diaphragmatic involvement	Shrinking lung syndrome
e. Airways involvement	Bronchiolitis obliterans

Pathogenesis

The pathogenesis of SLS remains elusive. The most recent case report supports the hypothesis of pleural inflammation as the main mechanism of lung restriction in SLS. For the first time, authors implemented the use of dynamic contrast-enhanced lung MRI revealing marked pleural and pericardial enhancement (Nemec *et al* 2015). The wider use of this imaging technique may reproduce similar findings thus helping us to

understand the origin of this syndrome. Rarity of SLS and absence of pathologic data have led to a number of speculative aetiologies for SLS (summarised in Table 2).

SLS was initially thought to be related to alveolar micro-atelectasis and hyaline membrane formation resulting from pulmonary surfactant deficiency. Later, Gibson *et al* demonstrated diaphragmatic dysfunction evidenced by abnormal transdiaphragmatic pressures. It was thought that diaphragmatic weakness was a consequence of pleural adhesions, however later studies failed to confirm the link between the pleural adhesion and diaphragmatic weakness. The literature contains a single post-mortem study by Rubin and Urowitz who found no evidence of pleural adhesions and concluded that SLS was not due to primary lung disease or to diaphragmatic dysfunction related to pleural adhesions.

Marten *et al* supported the theory of weakness of both inspiratory and expiratory muscles caused by SLE. This notion was later rejected by Laroche *et al* who studied 12 patients with SLS using more reliable measures of respiratory muscle function and found that the reduction of vital capacity (VC) was due to abnormal chest wall expansion of uncertain aetiology. The theory of steroid induced diaphragmatic weakness was rejected because of improvement in lung function on increased immunosuppression. Wilcox *et al* who assessed phrenic nerve function in 9 patients with SLE with diaphragmatic weakness found no causative link.

Ishii *et al* proposed an association between SLS and anti- Ro antibodies based on 4 cases in the literature although they did not suggest a putative mechanism. Toya *et al* given the increased frequency of pleuritic chest pain suggested interaction between pleural inflammation and diaphragmatic dysfunction through pain-induced reflex inhibition of diaphragmatic activation.

Overall, the cause of SLS seems to be interplay between diaphragmatic dysfunction and pleural inflammation.

Table 2: Proposed aetiologies for pathogenesis of SLS

Author	Proposed aetiology
Hoffbrand and Beck, 1965	Alveolar micro atelectasis and hyaline membrane formation from surfactant deficiency
Gibson <i>et al</i> , 1977	Diaphragmatic dysfunction secondary to pleural adhesions
Marten <i>et al</i> , 1983	SLE induced inspiratory and expiratory myopathy
Laroche <i>et al</i> , 1989	Abnormal chest wall expansion of unknown aetiology
Hardy <i>et al</i> , 2001	Neurogenic origin through phrenic involvement
Wilcox <i>et al</i> , 1988	Evidence against phrenic nerve neuropathy
Toya <i>et al</i> , 2009	Pain-induced reflex inhibition of diaphragmatic activation
Ishii <i>et al</i> , 2000	Association with anti-Ro antibodies
Nemec <i>et al</i> , 2015	Pleural and pericardial inflammation

Clinical features

SLS typically presents with dyspnoea of variable severity progressing from exertional breathlessness to dyspnoea at rest. Dyspnoea is generally worse in the supine position with abdominal paradox commonly seen. Pleuritic chest pain is often reported, whereas dry cough and fever are rarely seen. Orthopnoea may occur because of diaphragmatic weakness. Past medical history may reveal pleurisy and, less commonly, pericarditis and/or myopathy. Poor chest expansion, rapid shallow breathing, and use of accessory muscles are found on clinical examination. Lung auscultation is usually normal although bibasal crepitations can be heard in the presence of basal atelectasis.

Diagnosis

Elevation of the diaphragm is a universal radiographic finding. Pleural effusions, pleural thickening or atelectasis are other infrequent findings. Chest CT and lung V/Q scan show no evidence of parenchymal involvement or thromboembolism. Bronchoscopy and bronchoalveolar lavage are unrevealing. Lung biopsy,

open or transbronchial, demonstrated normal lung tissue and a case report of an open pleural biopsy to investigate the area of pleural thickening on chest X-ray, showed fatty tissue.

Pulmonary function tests (PFTs) are consistent with a restrictive pattern and reduced total lung capacity (TLC). Carbon monoxide gas transfer capacity (DLCO) is reduced but the KCO (i.e. corrected for alveolar volume) is often normal.

The principal advantages of volitional tests are that they give an estimate of inspiratory or expiratory muscle strength, are simple to perform, and well tolerated. Maximal inspiratory pressure (MIP) generated at the mouth is a measure of global inspiratory muscle strength and it is usually reduced in SLS patients. Maximal expiratory pressure (MEP) at the mouth is not affected by diaphragmatic function, and a pattern of reduced MIP and normal MEP is consistent with diaphragmatic weakness. However, MIP and MEP may underestimate respiratory muscle strength due to incomplete activation of the muscles during the manoeuvre; hence a sniff technique measuring nasal pressures produces more reliable estimation of the inspiratory muscles. The disadvantage of mouth and nasal sniff pressures is that they don't discriminate weakness between the different respiratory muscles.

To increase diagnostic accuracy, we can measure relaxed VC in the supine and erect position alongside MIP/MEP and a sniff manoeuvre to look for diaphragmatic weakness. To evaluate the diaphragmatic movements, which are commonly reduced in SLS, ultrasound or fluoroscopy can be useful.

Finally, blood tests show typically normal creatinine kinase levels except for patients with myositis secondary to SLE.

Treatment

To date there is no universally agreed treatment approach for SLS, due to the absence of randomised controlled trials of treatment for SLS, uncertainty of its cause and different therapeutic strategies proposed by different investigators. Most reports describe the efficacy of oral corticosteroids (20mg/day to 1mg/kg/day of prednisolone) often preceded by pulses of intravenous methylprednisolone. Symptomatic improvement of patients receiving high doses of steroid starts within 48 hours, although major response usually takes several weeks to months. An increase in lung volumes is usually observed on high dose steroids, although the timing of improvement is variable. In severe cases, immunosuppressive agents, such as cyclophosphamide, azathioprine, mycophenolate mofetil and methotrexate in conjunction with corticosteroids were used with variable success (Duron et al, 2016; Borrel et al, 2016). There were several case reports in the literature supporting the use of B cell depleting therapy (e.g. Rituximab) in refractory cases of SLS (Toya *et al* 2009).

Other therapies that were tried, include theophylline and high-dose β agonists, mainly employing their effect of improving diaphragmatic strength (Van Veen *et al* 1993, Thompson *et al* 1985). A 31% improvement in lung

capacity was observed in SLS patients receiving theophylline, which can be tried alone or in combination with steroids. The use of β -agonists in SLS comes from case reports and a decrease of diaphragmatic fatigue is observed through their positive inotropic effect.

In a case report of SLS, implementation of nocturnal non-invasive positive pressure ventilation (NIPPV) alongside immunosuppressive therapy led to diaphragmatic improvement, demonstrated by improved PFTs parameters (Panchabhai *et al* 2016).

Prognosis

The overall prognosis of this syndrome is good. There is evidence from previous case reports and series that subjective improvement on initiation of treatment can be observed in almost 80% of patients (Duron *et al*, 2016; Borrel *et al* 2016). Objective improvement measured by either improved pulmonary function tests or respiratory pressures is observed up to 20% of patients. Death due to respiratory failure or associated complications is rare (Karim *et al* 2002).

Conclusion

SLS affects a small proportion of lupus patients causing significant morbidity. It should be considered a possible diagnosis in lupus patients presenting with dyspnoea. The underlying aetiology remains elusive. Given its rarity, randomized controlled trials are unavailable and controversies about its pathogenesis and therapy persist.

Systemic lupus erythematosus: treatment

Karen Visser, Frédéric A. Houssiau, José Antonio P. da Silva, Ronald van Vollenhoven

A previous version was co-authored by Bernard R. Lauwerys, Frédéric A. Houssiau, mathias Schneider

LEARNING OBJECTIVES

- ➔ Select the best treatment for patients with simple and complex manifestations of systemic lupus erythematosus (SLE) including lupus nephritis (LN)
- ➔ Support your treatment decisions on the basis of evidence
- ➔ Appreciate the risks and side-effect profiles of commonly used medications for SLE
- ➔ Critically manage the risk factors for cardiovascular disease and other comorbidities
- ➔ Evaluate which drugs can be used during pregnancy and how to treat active SLE during pregnancy

Treatment of systemic lupus erythematosus (SLE) has several goals: (i) induction of a prompt response, aimed at controlling disease activity; (ii) maintenance therapy, aimed at maintaining the response and at preventing flares; and (iii) prevention and treatment of comorbidities (e. g. hypertension, diabetes mellitus, osteoporosis) and of drug-induced damage. The armamentarium of therapies for SLE include glucocorticoids, antimalarials, conventional synthetic immunosuppressive drugs as well as biologic therapies. During the last two decades, major improvements in the treatment of SLE can be mainly attributed to a better use of traditional immunosuppressive drugs. Although an array of new biological drugs has been developed and tested in the last decades and more are underway, only one new drug, belimumab, has been approved for the treatment of SLE.

The first part of this chapter is dedicated to review the scientific evidence for the use of different drugs; in the second part, we propose therapeutic protocols dealing with specific organ involvement; finally, comorbidities and non-adherence will be discussed. Specific treatment for the antiphospholipid syndrome is described in another chapter.

The reader is strongly encouraged to read the EULAR, EULAR/ERA-EDTA and ACR recommendations for the treatment of lupus and lupus nephritis (LN) (Bertsias, 2008; Bertsias, 2012; Hahn, 2012), and to integrate a treat-to-target approach in her/his daily practice (Mosca, 2012; van Vollenhoven, 2014).

1. THERAPEUTIC AGENTS

1.1 Glucocorticoids

Glucocorticoids (GCs) are the mainstay of treatment of SLE as induction therapy and to manage acute flares and have dramatically improved the prognosis of severe SLE. Thus, survival rates have increased from 50% at 3 years in the 1950s (Jessar, 1953) to 92% at 10 years in recent series (Cervera, 2003). GC regimens vary from low dose (0.1-0.2 mg prednisone/kg/day or equivalent) to moderate (0.2-0.5 mg/kg/day) or high (0.5-1 mg/kg/day) dose, according to the type of organ involvement, as discussed below. Of note, these dosages of GCs based on body weight and especially the high dose of 1mg/kg/day are not evidence-based. As much as the use of GCs has improved the outlook of SLE, limiting their use is of equal importance, since evidence is accumulating that GCs might contribute to irreversible damage (Al Sawah, 2015). Interestingly, the initial dose of prednisone in the first month of treatment is predictive of the prednisone doses over the following 11 months (Ruiz-Irastorza, 2016).

Intravenous (IV) pulse methylprednisolone therapy, mostly 500-1,000 mg daily for 1-3 days, was introduced in the 1970s (Cathcart, 1976) and is remarkably efficacious in critically ill patients (Isenberg, 1982), suffering renal impairment, central nervous system disease, severe arthritis, pleuropericarditis or thrombopenia, although the

jury is still out regarding the dose of IV methylprednisolone needed to achieve rapid control of activity (Franchin, 2006).

Tapering schedules are mainly based on physician's experience and clinical judgment. In the National Institute of Health (NIH) protocol for the treatment of lupus nephritis (LN), after three IV methylprednisolone pulses (1,000 mg/day for three days), patients were given oral prednisone 0.5 mg/kg/day for 4 weeks and the dose was further tapered by 5 mg every other day each week to a dose of 0.25 mg/kg every other day or the minimal dose required to control extra-renal disease (Austin, 1986; Boumpas, 1992; Gourley, 1996; Steinberg, 1991). In the Euro-Lupus Nephritis Trial, after three consecutive IV methylprednisolone daily pulses of 750 mg, patients were switched to oral prednisolone (mostly 0.5 mg/kg/day for 1 month; 1 mg/kg/day in severe cases) which was tapered by 2.5 mg/day every 2 weeks to reach a maintenance dose of 5-7.5 mg/day at 4-6 months (Houssiau, 2002). In a recent series of LN patients, induction therapy *without* oral steroids was given consisting of 2 pulses of IV methylprednisolone 500mg and 2 doses of 1 gram of rituximab given 2 weeks apart followed by mycophenolate mofetil. Although pioneering, this was not a randomized controlled trial and patients represented a population without much extra renal disease (Condon, 2013).

Many SLE patients are maintained for years on low dose GCs (between 2.5 and 7.5 mg prednisolone/day) (Badsha, 2002). Chronic use of high dose GCs is associated with increased risk of infection and metabolic (Cushingoid features, diabetes, cardiovascular events), musculoskeletal (myopathy, avascular osteonecrosis, osteoporosis) and other side-effects such as easy bruising and early cataract. Longitudinal cohort studies have confirmed that GCs contribute to damage accrual in SLE, as measured by the SLICC/ACR damage index (DI). The mean DI rose from 0.33 at baseline to 1.9 after 15 years of follow-up in an inception cohort and damage was considered as GC-related in 16% and 49% of the patients at baseline and last follow-up, respectively (Gladman, 2003). In another cohort, the accrual of organ damage was found to correlate with the mean daily prednisone dose, with the risk increasing for doses higher than 6 mg per day (Thamer, 2009). Finally, damage accrual was found to be associated with higher risk of mortality, every one point increase in DI being associated with a 1.32 times higher mortality during follow-up (Chambers, 2009). In these studies the possible confounding effect of disease activity itself should be noted (higher disease activity is associated with both higher dosages of prednisone and damage accrual) and despite statistical modelling remains difficult to completely correct for.

Taken together, while GC remain an inescapable therapy in severe acute SLE cases, many concerns are raised by patients and their physicians regarding their chronic use as maintenance therapy. As a consequence, patients should receive the lowest possible dose of GC for the shortest period of time. In this respect, other immunosuppressants, such as azathioprine or methotrexate can be efficacious GC-sparing agents, although robust data obtained from randomized trials are relatively scarce (Fortin, 2008). Recent data from the Belimumab trials suggest that belimumab can be a steroid-sparing agent in lupus patients, with more patients

who decreased oral GCs and less patients with increases in oral GCs in the belimumab groups (Van Vollenhoven, 2016). In patients requiring GC, adequate prevention of bone loss should be applied, keeping in mind that GC-induced osteoporosis is an early event. Patients must be immunized against influenza (every year) and *Streptococcus pneumoniae* (every 5 years) (Naveau, 2005).

1.2 Antimalarials

Antimalarials are widely prescribed to SLE patients. Hydroxychloroquine sulphate (HCQ) is the most frequently used, at doses ranging from 200 to 400 mg/day (maximum 6.5 mg/kg ideal body weight/day). Other antimalarials such as chloroquine (125-250 mg/day; maximum 4 mg/kg/day) and quinacrine (100 mg/day) are preferred for severe cutaneous cases (Okon, 2013). HCQ is an alkalinizing lysosomotropic drug that accumulates in lysosomes where it inhibits some important functions by increasing the pH. It can inhibit toll like receptor signalling, the accumulation of nucleic fragments in lysosomes, the autophagic degradation and it can inhibit the binding of beta-2-glycoprotein to phospholipids (Ponticelli, 2017). Of note, tobacco smoking reduces the efficacy of antimalarials (Ezra, 2012).

While mucocutaneous and articular manifestations are the original indications for the use of antimalarials in SLE, pivotal data have shown that these drugs are beneficial in a wider variety of disease manifestations. The Canadian Hydroxychloroquine Study Group placebo-controlled randomized study demonstrated that HCQ withdrawal in clinically stable SLE patients was associated with an increased flare rate (The Canadian Hydroxychloroquine Study, 1991; Tsakonas, 1998). In addition, uncontrolled data from the LUMINA cohort (LUpus in the MInorities, NAture versus nurture) indicated that therapy with HCQ independently reduces damage accrual (Fessler, 2005 ; Alarcon, 2007), including renal damage (Pons-Estel, 2009). Likewise, observational data from the Grupo Latino Americano de Estudio del Lupus suggested that HCQ improved survival rate (Shinjo, 2010), although critics have mentioned channelling bias as a limitation in these studies.

Besides better lupus disease control, antimalarials display many other interesting properties, such as lipid profile improvement (Tam, 2000), prevention of thrombotic events, influence on cardiovascular risk, and a beneficial effect on bone mineral density (Ruiz-Irastorza, 2006 and 2010; Espinola, 2002). A recent retrospective review of pregnancies in mothers with offspring affected by congenital heart block (CHB) suggests that HCQ use significantly reduces the recurrence of CHB (21.7% in non-HCQ users versus 7.5% in HCQ users) (Izmirly, 2012). Finally, HCQ whole blood measurements was recently found to be a reliable marker of adherence to therapy (Costedoat-Chalumeau, 2013). Conversely, low levels of HCQ suggesting poor adherence have been found to be predictive of flares (Costedoat-Chalumeau, 2007). Therefore, many experts currently advice to prescribe HCQ (minimum 200 mg/day) in all SLE patients, even in the absence of overt clinical manifestations (D'Cruz, 2001).

Antimalarials are considered safe and well tolerated and can be safely used during pregnancy. Side-effects include digestive intolerance (diarrhoea), skin rash, aquagenic pruritus, blue-grey or brown lower leg hyperpigmentation (Jallouli, 2013), cardiomyopathy, myopathy and retinopathy. Retinopathy can present with photophobia, blurred distance vision, missing or blacked out areas in the vision field (or while reading) and light flashes. Retinopathy is rare with HCQ at doses below 6.5mg/kg/day, and somewhat less exceptional with long-term chloroquine use. New data about the prevalence of retinopathy has led to a recent update of the American Guidelines of Ophthalmology for toxicity screening (Marmor, 2016). At the previously recommended doses of 6.5 mg/kg ideal weight/day the risk of retinal toxicity after 5 years is <1%, after 10 years <2%, but it appears to rise to almost 20% after 20 years. However, in patients with HCQ lower than or equal to 5 mg/kg, without signs of toxicity, the risk appeared much lower (Melles, 2014). Therefore, a maximum recommended dose of 5 mg/kg of observed (rather than ideal) body weight is proposed. In addition, a baseline fundoscopy and annual screening starting after 5 years, for patients on acceptable doses without major risk factors, is recommended. For patients on higher dosages or patients with risk factors more frequent examinations are recommended. Risk factors include age over 60 years, pre-existing macular degeneration, retinal dystrophy, obesity, liver disease and renal failure (Marmor, 2002; Mosca, 2009) and should be assessed regularly. Use of tamoxifen has been identified as an additional risk factor (Marmor, 2016). The rheumatology world has not yet adopted these new recommendations and some critical comments have been published.

In summary, antimalarials are safe and effective in treating musculoskeletal and mucocutaneous manifestations of SLE and reducing the risk of flares, and may have additional benefits in reducing organ damage in the long-term, allowing the reduction of GCs, and decreasing the risk for thromboses, atherosclerosis and osteoporosis.

1.3 Cyclophosphamide

Cyclophosphamide (CYC) was first used in SLE in the late 1970s at the Mayo Clinic as an oral drug to treat LN (Donadio, 1978). Sometimes oral CYC is still used for a limited time course (3 months; 1-2 mg/kg/day) as induction therapy (Mok, 2006; Ponticelli, 2010) but because of concerns regarding the side-effects of long-term exposure to oral CYC, such as alopecia, bladder cancer, haemorrhagic cystitis, bone marrow suppression, haematological malignancies, myelodysplasia and premature gonadal failure, most clinicians have moved to IV CYC.

The first IV CYC protocol was developed at the NIH and consisted of 6 monthly pulses of CYC (750-1,000 mg/m²) followed by quarterly pulses (at a similar dose) for 2 additional years, usually in combination with IV methylprednisolone pulse therapy and GCs (Austin, 1986; Boumpas, 1992; Gourley, 1996; Illei 2001). This protocol has been the standard of care for proliferative LN during two decades, as well as for severe non-renal lupus, despite the risk of severe infections linked to drug-induced neutropenia and other risks and side-effects.

The administration of anti-emetic drugs before pulse CYC reduces nausea and vomiting and IV hyper hydration and the use of 2-mercaptoethane sodium sulfonate (Mesna), which binds toxic metabolites, can be used to reduce the incidence of haemorrhagic cystitis. The use of MESNA is not strongly evidence-based, nor is the risk of bladder toxicity associated with IV CYC in rheumatic diseases as compared to the use in oncology, as elaborated in a review (Monach, 2010). The use can be considered on an individual basis, taking into account the dose and duration, oral versus IV CYC, other risk factors and the tolerability to hyper hydration. A major concern with this long-course IV CYC regimen is the risk of premature gonadal failure in female patients of child-bearing age, which is strongly dependent on cumulative dose but also on the age of the patient (Boumpas, 1993; Ioannidis, 2002; Katsifis, 2004). An increased incidence of cervical intraepithelial neoplasia in lupus women treated with high-dose IV CYC has also been reported (Ognenovski, 2004). This explains why a long-course of quarterly IV CYC pulses is not recommended anymore as maintenance therapy of LN (Bertsias, 2012; Hahn, 2012).

In order to reduce side-effects, a lower-dose IV CYC regimen (6 x 500 mg fixed dose every two weeks), followed by azathioprine (after 3 months), was developed at St-Thomas' Hospital in London (Houssiau, 1991; Haga, 1992) and further compared to a long-course IV CYC regimen in a controlled trial, the Euro-Lupus Nephritis Trial (Houssiau, 2002; Houssiau, 2004; Houssiau, 2010). Based on the positive results of this trial, the so-called "Euro-Lupus regimen" is now an accepted option for the treatment of proliferative LN (Bertsias, 2012; Hahn, 2012). While the original Euro-Lupus study represented mostly Caucasian patients with moderate LN, the Euro-Lupus regimen has also been shown effective in a population of more severe LN patients of more racially diverse background in a US-based study (ACCESS trial) (Wofsy, 2013, 2015). Of note, ethnicity might be of importance for the efficacy of IV CYC. Hispanic and black patients have shown lower response rates to IV CYC (in studies compared to MMF) (Isenberg, 2010). In Asian LN patients, the EURO-Lupus regime was evaluated against MMF without any observed differences (Rathi, 2016).

Finally, very high immunoablative doses of IV CYC have been tested in refractory lupus cases, with improvement in disease activity (Brodsky, 1998; Petri, 2003; Petri 2006).

1.4 Azathioprine

Azathioprine (AZA) is used in clinical practice as a GC-sparing agent in several autoimmune/inflammatory diseases, including SLE. The drug is transformed to 6-mercaptopurine (6-MP) and then to its active metabolites, thiosinic and thioguanilic acid (6 TGN), which incorporate into DNA, thereby causing DNA/protein crosslinks and interfering with nucleic acid structure. The daily dose of AZA is between 1 and 2.5 mg/kg. Gastrointestinal intolerance is the most common side-effect. Bone marrow suppression, increased risk of infections, hepatitis and hypersensitivity reaction are potentially severe but rare adverse events. Because allopurinol blocks xanthine oxidase (one of the enzymes that metabolizes 6-MP), these two drugs are generally

not combined. If both must be taken, the dose of AZA must be reduced by 50-75% to prevent bone marrow toxicity. In case of co-administration of AZA with warfarin, a higher dose of the anticoagulant may be required to maintain therapeutic INR levels (Ng, 2006).

Individuals who are completely deficient in thiopurine methyltransferase, the main enzyme responsible for metabolism of 6-MP (1/300) can develop severe pancytopenia on AZA. TPMT deficiency is not rare and some authorities recommend genotyping before starting AZA treatment ;the drug should not be prescribed in case of homozygous deficiency and the dose should be carefully titrated upwards in case of heterozygous mutations (Payne K, 2007). However, genotyping is not done routinely by many rheumatologists ; a frequent approach is to start and titrate therapy in steps from a low dosage (50mg) up to the desired dose and check tolerability and blood count after every increase, for example every two weeks.

AZA use has been best studied in LN, either as induction therapy (Grootscholten, 2006; Grootscholten, 2007) or as maintenance treatment (Houssiau, 2002; Houssiau, 2010b). Furthermore, it is effective as an immunosuppressive and steroid sparing agent in other manifestations of SLE. One of the advantages of AZA is its safety in pregnancy; the drug can be continued in pregnant LN patients who need long-term maintenance therapy, often as an alternative to mycophenolate mofetil (MMF) which must be stopped due to its teratogenicity (Perez-Aytes, 2008).

1.5 Methotrexate

Data on the use of methotrexate (MTX) in SLE derive from small cases series, uncontrolled studies and a few controlled trials (Fortin, 2008). MTX, at doses up to 15–25 mg/week, seems efficacious not only in the treatment of articular manifestations refractory to low-dose steroids and antimalarials, but also in the treatment of serositis, cutaneous manifestations, and other features of moderately severe systemic lupus. A systematic review on 3 RCTs and 6 cohort studies showed that MTX was associated with lower SLEDAI scores when compared to controls and significant reductions in corticosteroid use (Sakthiswary, 2014). Small case series suggest MTX may also work for lupus vasculitis and some haematological manifestations, and in a small number of cases it has been given intrathecal for central nervous system lupus (Winzer, 2010).

The safety profile of MTX in SLE patients is similar compared to rheumatoid arthritis (RA) patients. However, because disease-related renal impairment is more frequent in SLE, MTX dose reduction may be required in LN patients with renal failure. Although MTX is generally well tolerated, it can cause dyspepsia, headache, general malaise, increase in serum liver enzyme levels and bone marrow toxicity, the two latter side-effects requiring regular blood monitoring. Rarely, a dry non-productive cough can be the symptom of MTX-induced interstitial lung disease.

1.6 Mycophenolate mofetil

Mycophenolate mofetil (MMF) is a reversible inhibitor of inosine monophosphate dehydrogenase (IMP-DH) and has lymphocyte-selective cytostatic effects, inhibiting T and B lymphocyte proliferation. The drug, used at a dose between 1 and 3 g/day, was gradually introduced into the therapeutic armamentarium for SLE since the end of the 1990s (Glicklich, 1998; Gaubitz, 1999) and subsequently studied in several large randomized controlled trials (RCTs) in LN. These trials showed that MMF is efficacious as induction (Chan, 2000; Ginzler 2005; Ong, 2005; Appel, 2009) and maintenance therapy (Contreras, 2004; Dooley 2011; Houssiau, 2010b). MMF was further tested in open series of patients suffering from renal or non-renal disease (Karim, 2002; Bijl, 2003; Pisoni 2005). A recent cohort study showed its efficacy in refractory to standard of care non-renal manifestations and reduction of corticosteroid use (Tselios, 2016).

MMF side effects are generally moderate and rarely lead to treatment discontinuation. They mainly consist of gastrointestinal manifestations (diarrhoea, nausea, vomiting), hepatitis and anaemia, the latter mainly observed in patients with renal impairment. Other side effects such as pancreatitis and febrile pancytopenia have been observed rarely. The drug is strictly contraindicated in pregnancy (at least during the first trimester) because of proven teratogenicity, with peculiar involvement of the face (Perez-Aytes, 2008).

Recently, a new drug containing mycophenolic acid, the active metabolite of MMF, became available. One gram of mycophenolate mofetil corresponds to 720 mg of mycophenolate sodium. This new formulation may have better gastrointestinal tolerability (Budde, 2004) and was tested in LN (Zeher, 2011).

1.7 Calcineurin inhibitors

Calcineurin inhibitors (CNI) display two modes of action. First, they inhibit T-cell mediated responses, such as cytokine production (e. g. of IL-2), leading to reduced immune activation and glomerular immune complex deposition. Second, they stabilize the podocyte actin cytoskeleton thereby contributing to maintenance of the integrity of the filtration barrier and explaining their potent antiproteinuric effect in LN patients (Faul, 2008).

Cyclosporine A (CSA) has been used to treat a variety of clinical manifestations, as reviewed elsewhere (Griffiths, 2001; Morton, 2000) but has been best studied in LN, including membranous nephropathy. At an initial dose of 4-5 mg/kg/day, CSA was found as efficacious as IV CYC in a randomized trial performed in patients with proliferative LN (Zavada, 2010). The drug was also compared against AZA for maintenance therapy of LN (Moroni, 2006). It is not always well tolerated: transient increase in serum creatinine, hypertension, hypertrichosis, gum hypertrophy, tremor and seizures may occur (Conti, 2000).

Tacrolimus (TAC) is a macrolide compound isolated from a soil fungus found in Northern Japan and is now widely prescribed in transplantation. It has been tested in proliferative and membranous LN in Asian populations (Mok, 2005; Szeto, 2008; Miyasaka, 2009) and was found to have similar efficacy as MMF in a

randomized trial (Mok, 2016), although a trend towards more renal flares and functional decline was observed in the follow-up. Multi-target therapy, combining TAC, MMF and GC, was shown to induce a higher rate of early renal remission compared to IV CYC (Bao, 2008; Liu, 2015), with a note of caution regarding possible rebound proteinuria when TAC is withdrawn. A positive note is that TAC has no known negative effects on fertility and pregnancy. A new CNI, voclosporine, is currently being tested in LN in combination with MMF.

Current practice is not to use CNI as first therapy in LN due to their potential toxicity. They can be useful in selected cases with persistent proteinuria despite standard immunosuppression.

1.8 Thalidomide

Thalidomide (THA), formerly marketed as Softenon, was developed as an antiemetic drug to relieve morning sickness of pregnant women and as a sleeping pill. In the early 1960s, it was found to be dramatically teratogenic (phocomelia) and was withdrawn. Further studies have shown its efficacy in the treatment of leprosy and multiple myeloma. The mechanism of action of the drug is poorly understood, but it appears to display antiangiogenic effects. THA has been used in SLE since the early 1980s (usually 50 mg/day at night) and many studies have demonstrated its efficacy (Pelle, 2003; Coelho, 2005; Cuadrado, 2005). THA is mostly prescribed for severe chronic discoid lupus resistant to antimalarials, with usually very impressive results. Toxicity is the major limiting factor. Thus, polyneuropathy is frequent (at least 20% of patients), can be disabling and is mostly irreversible (Briani, 2004). Patients on THA require regular neurological assessments and electromyography. In some countries, a monthly negative pregnancy test is required before the drug can be prescribed and obtained. Relapses after discontinuation are frequent and may justify the use of a lower maintenance dose such as 50 mg three times weekly.

Immunomodulatory analogues of THA have been developed, such as pomalidomide and lenalidomide, which are purported to be more potent and less toxic than THA. Lenalidomide was recently studied in refractory cases of cutaneous lupus (Cortes-Hernandes, 2012).

1.9 Dapsone

Dapsone, (DAP), 4,4 – diaminodiphenylsulfone, is used in the treatment of dermatitis herpetiformis and as antimycobacterial drug in leprosy. The efficacy of the drug in SLE was suggested in case reports and small series (Fenton, 1986; Neri, 1999; Chang, 2011). DAP seems efficacious in treating bullous LE, subacute cutaneous lupus and mucosal ulcers. It is suggested to start with 100 mg daily and then to taper to the minimally efficacious dose in 2-3 months. DAP can cause nausea and dyspepsia. Major side effects include haemolysis, especially in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, and polyneuropathy. Methaemoglobinaemia is the rule in patients treated with DAP but is not, per se, a reason to withdraw therapy, except if it induces a decrease in haemoglobin.

1.10 Leflunomide

Leflunomide (LEF) is a synthetic isoxazole derivative of low molecular weight, with immunomodulatory and anti-inflammatory effects. Its efficacy in the treatment of rheumatoid arthritis and psoriatic arthritis is well established, and some data have been published on its efficacy in SLE (Remer, 2001; Tam, 2004) and even LN (Tam, 2006). In the absence of proper controlled trial its use should be limited to selected cases. Its pros and cons have been described by Wu, 2013.

1.11 Intravenous immunoglobulin

Intravenous immunoglobulins (IVIG) are used as rescue therapy in many refractory autoimmune diseases and some reports suggest its efficacy as treatment of difficult SLE cases (Sherer, 2006). It may be given at 1-2 g/kg/day for 2 consecutive days or 0.4 g/kg/day for 5 consecutive days, and can be repeated monthly as maintenance therapy. Treatment duration in reported series has varied from a few months to years. Except for a clear role in the treatment of SLE-related thrombocytopenia and/or haemolytic anaemia, no other clinical indications for IVIG are supported by strong evidence. IVIG has been used in the management of critically-ill SLE patients (Engel, 1999), but also as a treatment for mild to moderate SLE, in LN (RCT, Boletis, 1999), and for the prevention of recurrent pregnancy losses. Treatment with IVIG is associated with a small risk for thromboembolism but has otherwise surprisingly few side-effects. In contrast to conventional immunosuppressants, IVIG therapy does not increase the infection risk and may therefore be considered proposed in selected cases when concomitant infection cannot be ruled out. Also, IVIG are safe to use in pregnancy. Treatment cost and lack of evidence-based recommendations clearly limit their use.

1.12 Plasma exchange

Plasma exchange (PE) has an established role in the treatment of several autoimmune diseases and syndromes, such as Goodpasture syndrome and microangiopathic haemolytic anaemia. PE has been used to treat various manifestations of SLE over the past 35 years (Pagnoux, 2005), and case reports have suggested effectiveness in controlling severe disease activity, such as alveolar haemorrhage, catastrophic anti-phospholipid syndrome (Bortolati, 2009), neurological involvement (Bartolucci, 2007), haematological manifestations, pericarditis, myocarditis, nephritis, and vasculitis and severe SLE in pregnant patients with or without the anti-phospholipid syndrome (Zandman, 20015). However, a controlled trial comparing the efficacy of PE as treatment of LN in addition to IV CYC failed to show any benefit (Lewis, 1992). Moreover, in uncontrolled series PE in combination with IV CYC in SLE was associated with more severe infections and deaths compared to IV CYC alone (Aringer, 1998). Therefore, PE should probably only be considered as an adjunctive therapy in conjunction with high dose GCs and IV CYC in severely ill patients with SLE where specific pathophysiological mechanisms are activated, such as microangiopathy or catastrophic anti-phospholipid syndrome.

1.13 Haematopoietic stem cell transplantation

Haematopoietic stem cell transplantation (HSCT) is a high-risk procedure involving a conditioning regimen to eliminate autoreactive lymphocytes, followed by infusion of previously harvested autologous haematopoietic stem cells, with the aim of reconstructing the immune system. HSCT is becoming a therapeutic option in severe systemic sclerosis and has been used in severe refractory SLE (Alchi B, 2013). Procedure-related mortality is currently too high to propose HSCT, except within the frame of investigational protocols. Basically, only patients with very severe uncontrolled disease and at risk for permanent organ damage or death should be considered for this procedure.

1.14 Mesenchymal stem cell therapy

Several open studies suggest that allogeneic mesenchymal stem cell (MSC) therapy might be useful as adjunct therapy of lupus or LN (Liang, 2010; Sun, 2009; Sun, 2010). It should be stressed, however, that none of these trials were controlled and that the fate of MSC in vivo and their mechanism of actions are far from unravelled (Tyndall, 2010).

1.15 Targeted therapies

New insights in the pathophysiology of SLE and advances in biotechnology have led to a large number of targeted therapies that have been tested in SLE. So far, only the monoclonal anti-BLyS antibody belimumab has been approved for lupus by the EMA and the FDA. The anti-CD20 monoclonal rituximab has been used as an off-label drug, sometimes with apparent success in individual patients, but failed to demonstrate efficacy in randomized controlled trials. The design and choice of outcome measures in trials for a heterogeneous disease such as lupus is a challenge and may have contributed to negative results in the past. The use of some biologics was associated with a high rate of infectious side effects in SLE, such as the anti-CD20 monoclonal ocrelizumab and the anti-BLyS/APRIL receptor construct atacicept. Many targeted therapies are still under investigation in Phase II/III clinical trials. Table Ia lists the main clinical trials performed with biologics in SLE. Table Ib lists the trials that are still ongoing.

Table 1a: Targeted therapies in SLE – Trials in bold met their primary endpoint

Target	Molecule	Acronym First author, year	L/LN	Phase	N	Results
CD20	Rituximab	EXPLORER Merrill, 2010	L	II/III	257	No proven benefit vs SOC
		LUNAR Rovin, 2012	LN	III	144	11% more responders but not statistically significant
CD20	Ocrelizumab	BELONG Mysler, 2013	LN	III	381	Early termination – Infections (combo with MMF)
CD22	Epratuzumab	ALLEVIATE 1/2 Wallace, 2013	L	II	90	Early termination – No drug supply
		EMBLEM Wallace, 2014	L	IIb	227	More BICLA responders
		EMBODY 1	L	III	786	No benefit vs SOC
		EMBODY 2	L	III	788	No benefit vs SOC
BLyS	Belimumab	BLISS-52 Navarra, 2011	L	III	865	More SRI responders
		BLISS-76 Furie, 2011	L	III	826	More SRI responders
		BLISS-SC Stohl, 2017	L	III	836	More SRI responders
	Atacicept	Ginzler, 2012 Isenberg, 2015 APRIL-SLE (75mg arm)	LN	II/III	6 461	Early termination – Infections Results of 75mg arm, no effect on flare rate, 2 deaths in 150mg arm
	Tabalumab	ILLUMINATE-1 Isenberg, 2016	L	III	1164	No more SRI-5 responders
		ILLUMINATE-2 Merrill, 2016	L	III	1124	More SRI-5 responders in Q2W arm
IFNa	Sifalimumab	Merrill, 2011	L	I	33	Safe profile, inhibition type 1 IFN signature
	Sifalimumab	Kamashta, 2016	L	IIb	431	More SRI responders all dosages
	Rontalizumab	ROSE Mc Bride, 2012	L	II	238	More SRI responders in ≥10 mg pred
	IFNKinoid	Lauwerys, 2013b	L	I/II	28	Down-regulation of IFN signature
IFN receptor	Anifrolumab	Furie, 2017	L	IIb	305	More SRI-4/GC taper responders
IL6	Sirukuma	Rovin, 2016	LN	II	24	No more renal response
TWEAK	BIIB023	ATLAS	LN	II		Early termination - Inefficacy
CD28	Abatacept	Merrill, 2010	L	IIb	175	No less BILAG A/B flares
		Furie, 2014	LN	II/III	298	No more renal responses
		Wofsy, 2013a				Alternative analysis: pos result
		ACCESS	LN	II	134	No benefit vs SOC (GC+EL IV CYC)
		Wofsy, 2013b				
CD40L	BG9588	Boumpas, 2003	L			Early termination – Thrombosis
	IDEC131	Davis, 2001	L	II	85	No benefit vs SOC

L: SLE; LN: lupus nephritis; N: number of patients included; SOC: standard of care; NS: not significant; MMF: mycophenolate mofetil; BICLA: British Isles Combined Lupus Assessment; SRI: Systemic lupus erythematosus Responder Index; IFN: interferon; BILAG: Bursitis Isles Lupus Assessment Group index; GC: glucocorticoids; EL: Euro-Lupus; IV: intravenous; CYC: cyclophosphamide.

Table 1b: Targeted therapies in SLE – ongoing trials

Target	Molecule	Acronym	L/LN	Phase	Description
CD20	Rituximab	RITUXILUP	LN	III	RTX + IV MP + MMF vs GC + IV MP + MMF induction (NCT01773616)
		RING	LN	III	RTX for persistent proteinuria despite 6 months of standard immunosuppression (NCT01673295)
	RTX/BEL	CALIBRATE	LN	II	RTX + CYL vs RTX + CYC + BEL safety (NCT02260934)
BLyS	Belimumab	EMBRACE	L	III	BEL in SLE black race (NCT01632241)
	Belimumab	BLISS-LN	LN	III	BEL + CYC or MMF induction vs placebo. BEL + AZA or MMF maintenance vs placebo (NCT01639339)
	Atacicept	ADDRESS II	L		NCT01972568)
IFN receptor	Blisibimod*	CHABLIS-SC I	L	II	Sc BL in addition to SOC (NCT01395745, NCT02074020)

**Press release Nov 2016 : CHABLIS-SCI has failed to reach the primary outcome*

1.15.1 Anti-B-cell therapies

Rituximab (RTX) is an anti-CD20 chimeric mouse/human B-cell depleting monoclonal antibody widely used for treatment of B-cell lymphoma, rheumatoid arthritis and granulomatosis with polyangiitis (formerly called Wegener's disease). CD20-negative plasmacytes and long-lived plasma cells are not affected by RTX treatment, thereby explaining why serum immunoglobulin titres rarely drop and why specific immune protection (e. g. against tetanus toxoid) is maintained. RTX was first tested by several expert groups as rescue therapy for

lupus and LN patients refractory to standard immunosuppression (Looney, 2004; Anolik, 2004; Leandro, 2002; Gunnarsson, 2007; Tokunaga, 2007; Jonsdottir, 2008; Diaz-Lagares, 2012). Two regimens have been used, the so-called lymphoma regimen (375mg/m² of BSA every week for four consecutive weeks, together with IV CYC) or the rheumatoid arthritis regimen (1 gm, twice, two weeks apart, without IV CYC). These small series suggested that RTX can be very efficacious in refractory lupus, with an effect on serological parameters, clinical outcomes, and renal biopsy. Rituximab has an acceptable safety profile, although a concern has been raised based on two cases of progressive multifocal leukoencephalopathy (Molloy, 2012). However, since that initial report no further cases have been published. B-cell depletion usually occurs within 2 weeks after the first infusion and B-cell repopulation after 3 to 40 months. Flares of disease activity have been reported in about 40% of treated patients, mostly concomitant with B-cell reconstitution. Retreatment with RTX was found to be efficacious and safe (Turner-Stokes, 2011). However, it is not clear whether patients should be pre-emptively re-treated at the time of reconstitution of B-cells. Based on this experience two randomized clinical trials were done: EXPLORER in general lupus (Merrill, 2010a) and LUNAR in LN (Rovin, 2012). Both studies, in which RTX was used as an add-on therapy, failed to show superiority of RTX over standard of care. These negative results, although they may well indicate that RTX is not truly effective in SLE, have been attributed to a number of limitations in study design, such as the selection of inadequate outcome measures and co-medications that may have masked the real benefit of RTX. Two studies are in the pipeline to further define the role of RTX in the treatment of LN. One, entitled RING, is testing the hypothesis that RTX is efficacious in LN patients who failed to achieve a sufficient renal response after at least 6 months of standard immunosuppression. The other, entitled RITUXILUP, is based on the results of an open series of 50 LN patients treated with an oral GC-free regimen, i. e. two pulses of 500 mg IV methylprednisolone and two doses of 1 g RTX, both given two weeks apart, followed by MMF. Renal response rate in these patients, who did not receive oral GCs, was similar to that reported in trials using standard GC therapy (Condon, 2013). The currently recruiting RITUXILUP randomized trial is aimed at testing the non-inferiority of RTX over oral GCs in LN patients treated with two pulses of 500 mg IV methylprednisolone and MMF.

Ocrelizumab (OCR), a humanized anti-CD20 monoclonal antibody, was tested in the BELONG LN trial, as an add-on induction therapy superimposed to GCs and MMF or GCs and Euro-Lupus IV CYC. The trial was terminated early due to a high rate of serious infections in the MMF/OCR group (Mysler, 2013).

Epratuzumab (EPR) is an anti-CD22 monoclonal antibody that acts as a CD22/BCR modulator. More specifically, binding of EPR to CD22 favours the co-localization of CD22 with the BCR, thereby promoting the inhibitory effect of CD22 on BCR signalling (raised threshold). B-cell depletion is much less stringent with EPR compared to RTX. EPR was first tested in ALLEVIATE-1 and ALLEVIATE-2, which were prematurely stopped due to drug supply issues but showed some efficacy (Wallace, 2013). In ENBLEM, a Phase IIb placebo-controlled dose-ranging randomized short-term (12 weeks) trial using a composite endpoint as primary outcome

measure, the BILAG-based Combined Lupus Assessment (BICLA), a beneficial effect was observed in patients given a cumulative dose of 2,400 mg (Wallace, 2014). However, EPR failed in the two pivotal phase III EMBODY studies.

1.15.2 Anti-cytokine therapies

Belimumab (BEL) is a fully humanized monoclonal antibody that binds BLyS (B cell activating factor), a cytokine that stimulates B-cell survival, development and differentiation into plasma cells. Increased levels of BLyS are observed in lupus prone mice as well as in SLE patients. After a promising Phase II dose-ranging trial (Wallace, 2009), two multinational pivotal Phase III trials (BLISS-52 and BLISS-76) demonstrated a statistically significant benefit for the addition of BEL to standard of care in terms of reducing disease activity, flare rates and GC sparing (Navarra 2011; Furie 2011). Both BLISS trials used as primary endpoint a new composite index named the Systemic Lupus Erythematosus Responder Index (SRI) that combines the SELENA-SLEDAI with the British Isles Lupus Assessment Group (BILAG) and the Physician's Global Assessment. Patients with severe active LN and CNS disease were excluded from both trials. Despite a high response rate induced by standard of care, both trials reached their primary endpoints, as did the BLISS-SC trial in which subcutaneous belimumab was tested (Stohl, 2017). Post-hoc analyses indicated that BEL was more efficacious in patients with higher disease activity, anti-dsDNA positivity, low complement or GC treatment at baseline (van Vollenhoven, 2012). Another post-hoc analysis showed that BEL was most effective in musculoskeletal and mucocutaneous domains (Manzi, 2012). While BEL was EMA-approved in 2011 for the treatment of lupus patients with clinically and serologically active disease and inadequate response to standard therapies, the optimal place of BEL remains to be further tuned (Hahn, 2013). Reassuring long-term safety data are now available (Ginzler, 2014) and a LN trial and a trial in patients of black ethnicity is currently in the pipeline. In serologically active anti-dsDNA positive patients with persistent disease manifestations despite low-dose GCs, HCQ and another immunosuppressant, a course of BEL is warranted with re-evaluation after 6 months. Of note, 1 case of progressive multifocal leukoencephalopathy has been reported in a belimumab-treated patient (Fredericks, 2014).

Other BLyS blocking agents are currently being tested, such as atacicept, a receptor construct that inhibits BLyS and APRIL (Ginzler, 2012) or blisibimod (anti-BLyS peptibody). Development of tabalumab (a monoclonal antibody targeting soluble and membrane-bound BLyS) was halted based on the fact that only one of the two pivotal Phase 3 trials met its primary outcome (Merrill, 2016; Isenberg, 2016).

Type I interferons (IFN) play a pivotal role in the pathogenesis of SLE (Rönnblom, 2006). Several molecules were currently developed to block this pathway (Lauwerys, 2013a). A RCT with the anti-IFN monoclonal rontalizumab failed to demonstrate clinical efficacy (McBride, 2012), but small studies with sifalimumab (anti-IFN α) looked promising (Merrill, 2011; Petri, 2013) and a large phase II trial achieved its primary endpoint

(Khamashta, 2016). The IFN α kinoid (a biomolecule designed to induce natural immunity against the cytokine) did not show clinical efficacy in a very small trial (Lauwerys, 2013b). The anti-IFN receptor monoclonal anifrolumab raises many hopes, based on positive Phase II results across several outcome measures. Two dosages (300mg and 1000mg) were tested against placebo in moderate- to severe lupus in addition to standard therapy. The primary endpoint, an SRI response with sustained reduction of steroids <10 mg/day occurred more frequently with both doses and achieved statistical significance with the 300 mg dose, and several secondary outcomes were also met (Furie, 2017). A prespecified secondary analysis in the type 1 interferon “high” population (those with higher IFN-related gene transcripts in peripheral blood leukocytes) showed even stronger results. Herpes zoster and influenza infections were reported more frequently in the anifrolumab groups. A phase III trial is ongoing.

Anti-IL6 sirukumab (Szepietowski, 2013), anti-IL6 receptor tocilizumab (Illei, 2010) and anti-TWEAK BIIB023 were all tested in very small trials but are unlikely to be developed further in SLE. Anti-TNF therapies have never been properly evaluated in SLE, but some experiences with infliximab in a few refractory cases suggested unacceptable safety risks (Aringer, 2009).

1.15.3 Inhibition of co-stimulatory molecules

Activation of (autoimmune) B cells and production of (auto)antibodies depend on optimal co-stimulation through several pairs of transmembrane proteins, such as CD40/CD40L and CD80-86/CD28. Inhibition of these pathways has therefore been tested in SLE.

Two different humanized monoclonal antibodies targeting CD40L have been developed: BG9588 and IDEC 131. A study of the BG9588 monoclonal anti-CD40L antibody in SLE patients with diffuse proliferative glomerulonephritis was terminated early because of thrombotic events, despite an observed reduction of proteinuria, haematuria and anti-dsDNA antibodies (Boumpas, 2003). The anti-CD40L monoclonal IDEC 131 was safe in a Phase I trial (Davis, 2001) but not superior to placebo in a Phase II study (Kalunian, 2002).

Abatacept (ABA) is a CTLA4-Ig fusion protein that binds to CD80/86, thereby preventing its interaction with CD28 on T-cells. The drug is approved for RA. A RCT with abatacept in non-renal SLE failed (Merrill, 2010). ABA was not superior to placebo in LN patients on a background of MMF and GCs for the induction of a complete renal response at 12 months (Furie, 2014). However, using other definitions of renal response, differences in favour of ABA were seen (Wofsy, 2013a), but in a subsequent trial ABA was again not superior to placebo (when given on a Euro-Lupus IV CYC/AZA background) (Wofsy, 2013b).

1.15.4 Other new therapies

Laquinimod (LAQ) is an antigen-presenting cell modulator that skews T cells towards an anti-inflammatory phenotype characterized by increased production of IL-10 and down-regulation of proinflammatory cytokines.

In a small randomized controlled trial, LAQ was found to induce more renal remission compared to placebo, but the difference was not statistically significant (Jayne, 2013).

Lupuzor (LUP) is a peptide (also known as P140) originating from the small nuclear ribonucleoprotein U1-70K. It was shown to display tolerogenic and immunomodulatory effects in preclinical lupus models, i. e. inhibition of T-cell reactivity against self-peptides. It was recently tested in SLE patients and found to induce significantly more SRI responses compared to placebo (Zimmer, 2013).

1.16 Hormonal contraception and hormonal replacement therapy

The use of oestrogens in SLE patients raises safety concerns due to the theoretical risks of disease flares and thromboembolic complications. Two randomized controlled trials, performed in patients with inactive or stable disease without a history of thrombosis, suggest that the use of combined oral contraceptives, containing 30-35 mcg of ethynyl oestradiol, does not increase the incidence of flares, nor the rate of thrombotic events (Petri, 2005; Sanchez-Guerrero, 2005). In patients with the antiphospholipid syndrome (excluded in the study by Petri et al., but not in the trial performed by Sanchez-Guerrero et al.) and/or a history of thrombosis, preference must however be given to other forms of contraception (Culwell, 2009). For patients with SLE in need of chronic anticoagulation a progestin-releasing intrauterine device is likely the ideal contraceptive method.

Prior to the unexpected early termination of the Women's Health Initiative (WHI) trial of continuous conjugated equine oestrogens (CEE) and medroxyprogesterone acetate (MPA), the prevailing view was that hormone replacement therapy (HRT) was a low-risk intervention. Studies in SLE patients, questioning the safety of hormone replacement therapy (HRT) mainly stem from that era. Nowadays, risks (including breast cancer) and potential benefits of HRT need to be carefully weighed on the basis of individual patient characteristics. In SLE, in the HRT-SELENA trial, 0.625 mg of conjugated oestrogen daily plus 5 mg of medroxyprogesterone for 12 days per month was compared to placebo. Severe flares were not more frequent in the treated group but there were significantly more mild and moderate flares (relative risk: 1.34). Moreover, as in the general population, thromboembolic events were more common, although the difference was not statistically significant (Buyon, 2005). Of note, the trial excluded patients with high-titre anticardiolipin antibodies, lupus anticoagulant, or a previous history of thrombosis, who should not be given HRT. This said, HRT studies in SLE have been performed with oral oestrogens, and it is not known what the effect is of currently available regimens.

2. THERAPEUTIC PROTOCOLS FOR SPECIFIC ORGAN INVOLVEMENT

The therapy of SLE must be chosen based on the complexity of the disease and individual patient characteristics. International organizations such as the European League Against Rheumatism EULAR and the American College of Rheumatology ACR have issued treatment recommendations which may be helpful to the clinician and ensure uniform standards of care (Bertsias, 2008; Bertsias, 2012; Hahn, 2012). Treatment of SLE is guided by the type and the severity of each disease manifestation. Unless biomarkers become available that will allow us to predict to which drug a given SLE patient will respond, we mostly use a “trial and error” approach, of course with full knowledge of available data. Thus, systemic treatment of mild SLE, such as mild mucocutaneous or musculoskeletal involvement, is based on the administration of a short-course of low-dose GCs (0.1-0.2 mg/kg/day) and longer-term antimalarial drugs (mainly HCQ 200-400 mg/day). As already discussed, withdrawal of GCs is a priority and antimalarials are therefore often prescribed long-term irrespective of disease severity. Moderately severe SLE (e. g. more severe mucocutaneous and musculoskeletal disease or serositis) is generally treated with a short-course of medium dose GCs (0.2-0.5 mg/kg/day), promptly tapered to lower dose. In patients who are GC-dependent (i. e. whose disease tends to relapse as soon as the dose of GCs is decreased), it is advised to start a steroid-sparing immunosuppressant, the choice of which depends on the type of organ involvement. In case of arthritis, MTX (or LEF) may be preferred; in case of haematological disease or serositis, AZA might be a good candidate, as well as BEL in selected cases. Severe lupus (e. g. proliferative lupus nephritis, CNS involvement or severe thrombocytopenia) is best treated by a combination of pulse IV methylprednisolone followed by oral GCs (0.5 mg/kg/d) and MMF or IV CYC to induce a prompt response. When this goal is achieved, maintenance therapy with the less toxic immunosuppressant (AZA, MMF) is mandatory, given the high relapse rate. Refractory lupus needs special attention and is likely best managed in expert centres. For such patients, RTX and other biologic therapies are additional options. The following paragraphs specifically deal with certain organ involvements and summarize our best knowledge. They should not be applied “à la lettre” but should serve as a guide for optimal care. Of note, treatment of the antiphospholipid syndrome associated with SLE is discussed in another chapter.

2.1 Renal involvement

When untreated, LN may lead to renal failure with a major impact on survival and quality of life. Renal damage is a predictor of mortality in SLE and recurrent flares are associated with worse long-term outcomes (Bruce, 2015). In most cases a renal biopsy is pivotal to guide therapy. Glomerular lesions are graded according to the International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification criteria (Table II) (Weening, 2004). Importantly, not all LN patients need to be treated aggressively, and renal pathology may avoid both under- and overtreatment. Thus, patients with Class I or II LN should be treated by optimal renal protection (ACEI/ARB) and HCQ and do not need immunosuppression, in contrast to patients

with proliferative disease (Class III and IV). Pure membranous LN (Class V) raises some specific treatment issues.

Table II: Implication of histology grading for the therapy of LN

ISN/RPS	Pathology	Signs	Risk for ESRD	Treatment
I	No hypercellularity Mesangial ID	Low proteinuria	Very low	ACEI/ARB HCQ
II	Mesangial hypercellularity Mesangial ID	Low proteinuria	Very low	ACEI/ARB HCQ
III/IV	Endo/extra capillary hypercellularity Subendothelial ID	Proteinuria Renal impairment	10-20% with treatment; high risk without treatment	ACEI/ARB HCQ GC and other IS
V	Widening of BM Spikes Sub-epithelial ID	Proteinuria Renal impairment	<10%	ACEI/ARB HCQ GC and other IS (selected cases)

ISN/RPS: International Society of Nephrology/Renal Pathology Society; ESRD: end-stage renal disease; ID: immune deposits; ACEI: angiotensin-converting enzyme inhibitor; ARB: Angiotensin receptor blockers; HCQ: hydroxychloroquine; GC: glucocorticoids; IS: immunosuppressant; BM: basement membrane.

The main treatment goal in LN is to achieve a prompt response because absence of an early response (6 months) is a poor long-term prognostic factor (Houssiau, 2004; Tamirou, 2016). It was recently demonstrated in two studies that achievement of proteinuria < 0.7-0.8 g/day at 12 months was the best predictor of long-term renal outcome (Dall'Era, 2015; Tamirou, 2015). The current paradigm is to induce a response with an intensive approach using potentially toxic drugs for a short period of time and to maintain the response with a less aggressive immunosuppressant for the long-term. This said, complete renal response rates after 6 months of induction therapy remain low with current therapies (in most studies below 30%), which means that there is room for improvement. Similarly, relapses occur in more than 20-40% of patients (according to length of follow-up) despite maintenance therapy, indicating that further research is needed. Prognostic factors include non-white race, poor socioeconomic status, uncontrolled hypertension, high activity and chronicity on biopsy, renal impairment at baseline and poor initial response to therapy (Austin, 1995). Existing guidelines for the treatment of lupus nephritis include the ACR and EULAR/ERA-EDTA recommendations (Bertsias 2013, Hahn 2012). A comprehensive overview of LN treatment was recently published (Zampeli, 2017).

2.1.1 Induction treatment

Three different immunosuppressive regimens can be proposed for patients with Class III/IV LN, namely

- i) NIH IV CYC (0.75-1g/m² monthly x 6) combined with IV methylprednisolone and oral GCs (Austin, 1986; Boumpas, 1992; Gourley, 1996; Illei, 2001);
- ii) Euro-Lupus IV CYC (500 mg every two weeks x 6) combined with pulse IV methylprednisolone (3 daily pulses of 750 mg) and oral GCs (prednisolone 0.5 mg/kg/d) (Houssiau, 2002) or
- iii) MMF (2-3 g/day) (Chan, 2000; Ginzler, 2005; Ong, 2005; Appel, 2009).

The Euro-Lupus Trial showed similar efficacy between option i and ii, although the patients were mostly of Caucasian descent and with moderate nephritis (Houssiau, 2002). Another aspect in the original trial was the start of maintenance therapy with AZA, which started after 3 months in the low dose CYC group and after 12 months in the high dose CYC group where 2 extra quarterly pulses of CYC were given. Results after 10 years' follow-up have been published and are comparable (Houssiau, 2010). Finally, it should be stressed that the Euro-Lupus regime is also efficacious in LN patients presenting with more severe disease at baseline and in a more racially diverse LN population, as recently demonstrated in the US-based ACCESS trial (Wofsy, 2013).

All RCTs comparing NIH IV CYC to MMF concluded that the two regimens are equally toxic and efficacious, at least in the short and medium term, even for severe LN patients (Tang, 2008; Rovin, 2013; Appel 2009; Ginzler 2005). This was also the conclusion of a Cochrane systematic review (Henderson, 2012) comparing MMF to CYC as induction (and also MMF vs AZA as maintenance). A recent Bayesian network analysis even showed higher remission rates and more favourable safety profile with MMF (Lee, 2015). That said, MMF is more patient-friendly, does not interfere with fertility and can be readily monitored by measurements of mycophenolic acid serum titers. Lower response rates to IV CYC (compared to MMF) have been reported in Hispanics and Blacks (Isenberg, 2010). This does not mean that IV CYC should be withdrawn from the armamentarium of LN. Very long-term data (at least 10 years) are only available so far for LN patients treated with IV CYC. Importantly, IV CYC treatment ensures optimal adherence, especially the Euro-Lupus IV CYC regime because patients are seen every fortnight in the clinic. The Euro-Lupus regime was also tested against MMF in an Asian LN population and no differences could be observed (Rathi, 2016).

AZA induction therapy has been compared to NIH IV CYC. While no more cases of ESRD were observed in the AZA group, there were more renal relapses and more chronic changes on repeat renal biopsies in the AZA group (Grootscholten, 2006; Grootscholten, 2007; Arends, 2012). Except in selected cases (e. g. for toxicity concerns regarding IV CYC and MMF or because of onset of LN during pregnancy), AZA is not recommended as induction therapy (Bertsias, 2012).

Tacrolimus has been studied against MMF in Chinese patients with AZA maintenance and appeared non-inferior, although a trend towards more renal flares and renal function decline with tacrolimus was observed during the follow-up 5 years (Mok, 2016). The combination of MMF and TAC was superior tot IV CYC for achieving a complete renal remission in another Asian study (Liu, 2015).

2.1.2 Maintenance treatment

Two drugs are mainly used for maintenance therapy in LN: AZA (ideally 2-2.5 mg/kg/day) and MMF (usually 2 g/day). The long-term quarterly high-dose IV CYC NIH maintenance regime cannot be recommended anymore, given an unacceptable rate of premature gonadal failure (Boumpas, 1993). AZA and MMF have a very reasonable toxicity profile for long-term use and have been compared in two RCTs : MAINTAIN (Houssiau, 2010b; Tamirou 2016) and ALMS (Dooley, 2011). While in the latter, a multi-ethnic study, MMF was shown superior to AZA to prevent renal relapses, this was not the case in the former, an European-based trial with mainly Caucasian patients. The design of these two trials are different and their results should therefore not be compared head-to-head. Rather, we would suggest, as recommended by the EULAR (Bertsias, 2012) and the ACR (Hahn, 2012), that the two drugs can be used as maintenance therapy of LN, an opportunity since not all patients will respond to the same drug. Patients planning pregnancy should not use MMF which is absolutely contraindicated, at least during the first 3 months. Calcineurin inhibitors are an alternative to AZA or MMF in selected cases. Their stringent antiproteinuric effect, through their effect on podocytes is of interest, as well as the possibility to use them during pregnancy. Nevertheless, their toxicity profile (hypertension, renal impairment, effects on lipid profile, tremor, hirsutism, gum hyperplasia, etc.) and the rebound of proteinuria after their withdrawal explain why we do not propose them as first line maintenance drugs in LN.

An understudied topic is when to stop immunosuppression, as very few studies have addressed this pivotal question (Moroni, 2006). In the absence of data it seems prudent to maintain AZA or MMF for at least several years after remission, or at least very good disease control, is achieved. Of course, each patient's individual situation must be considered. Most experts feel that GCs can be discontinued relatively soon after a full response has been achieved, but this will also depend on the presence of extra-renal manifestations.

2.1.3 Membranous LN

Membranous lupus glomerulonephritis (ISN/RPS Class V LN) is characterized by sub epithelial immune deposits. It can exist in isolation or be associated with proliferative Class III/IV disease. In the latter cases, most physicians consider that the presence of proliferative lesions guides therapy. Moreover, patients treated for proliferative disease sometimes switch to membranous LN, discovered on repeat kidney biopsy performed because of persisting proteinuria.

Treatment of pure membranous LN does probably not differ from that of idiopathic membranous nephropathy. Based on the nephrology experience, for patients with mild proteinuria a “watchful waiting” approach with optimal blockade of the angiotensin renin aldosterone system is usually appropriate. In patients with severe proteinuria, immunosuppressants are usually added, combining GCs with either MMF, AZA or CNI. In a controlled trial performed at the NIH, patients with pure membranous LN received (A) CSA

and alternate-day GCs; or (B) alternate-month IV CYC for 6 doses and alternate-day GCs; or (C) alternate-day GCs alone. Regimes (A) and (B) were both found superior to (C) at one year, but, interestingly, while the effect was prompter with CSA, relapses were more frequent than in the IV CYC group (Austin, 2009). A subset analysis performed in the 84 pure membranous LN cases randomized in two large recent randomized LN trials comparing MMF and IV CY (Ginzler, 2005; Appel, 2009) revealed that both drugs were equally effective at 24 weeks (Radhakrishnan, 2010). Subcutaneous heparin is used in the prevention of thrombosis in patients with nephrotic syndrome and low serum albumin (< 2 g/dL).

2.1.4 Biologics in LN

As already alluded to, none of the biological therapies tested so far has demonstrated effectiveness in LN as add-on therapy, superimposed to standard of care. The future of targeted therapy in LN may therefore well be elsewhere, e. g. as a GC-sparing agent or for the treatment of refractory cases not responding to at least 6 months of standard immunosuppression, as currently tested in the RING study.

2.1.5 Optimal care for LN patients

The principles of optimal care for LN are summarized in Table III

Table III: Optimal care for LN patients

Early detection and complete baseline evaluation, including renal biopsy
Education on the long-term risks and the treatment goals
Follow-up in specialized Lupus Clinics
Identification of non-adherence to therapy
Minimize glucocorticoids
Early treatment switch in case of insufficient response after 6 months
Optimal renal protection (BP: $\leq 120/80$ mm Hg; antiproteinuric therapy)
Prevention of cardiovascular disease (smoking cessation, weight control, BP control, lipids)
Prevention of GC-induced bone loss
Immunization (HPV, influenza, <i>Streptococcus pneumoniae</i>)

2.1.6 Renal replacement therapy

Between 10 and 20% of LN patients will require renal replacement therapy (RRT), the lower figures being observed in RCTs and the higher in the real world. It is of critical importance to look for these data in the very long-term, since LN usually starts in young patients. In some very refractory cases, it may be wiser to step down immunosuppression, when the battle is lost anyway, in order to avoid further toxicity. Haemodialysis is preferred by certain expert nephrologists based on a higher rate of infectious events in LN patients treated by peritoneal dialysis, but this view is not unanimously shared (Rietveld, 2008). Most LN patients with ESRD are suitable candidates for renal transplantation (RT) (Nossent, 1991). Some recommend waiting to transplant to

allow for quiescence of the SLE-related immune activity. Other data suggest that longer waiting times to transplant may be associated with equivalent or worse, not better, graft outcomes among LN-ESRD patients (Plantinga, 2015). More studies are needed to clarify the potential confounding effect of lupus disease activity on the observed associations. When feasible, the ideal setting is pre-emptive grafting (before ESRD is reached) with a living donor (Lochhead, 1996; Ward, 2000). Recurrence of LN in the graft is possible but rare (1-4%) (Moroni, 2005; Stone, 1997). On the whole, graft survival has been reported to be similar compared to other ESRD groups and lower than in other glomerular diseases. The factors associated with a poor outcome of RT are listed in Table IV.

Table IV: Poor prognostic factors in renal transplantation for SLE

Cadaveric transplantation	Living donor RT is associated with better graft survival
Ethnicity	Black patients have a poorer graft survival
Anti-phospholipid positivity	Thrombotic events are much more frequent in RT recipients with APL antibodies
Disease activity after RT	Persistent lupus disease activity requires further immunosuppression but is associated with more infectious events
Clinical status at the time of RT	Poor general medical condition deleteriously impacts graft and patient survival after RT
Dialysis duration	Long-term dialysis risk factor for graft failure? (unclear)

2.2 Central nervous system involvement

Neuropsychiatric involvement in SLE (NPSLE) is characterized by a variety of clinical manifestations and its pathogenesis and assessment are complex and debated. As a consequence, designing controlled trials is extremely difficult and treatment of NPSLE strongly relies on the treating physician's clinical experience (Hanly, 2005). Treatment of NPSLE can be symptomatic, based on experience with, for example, anticonvulsants, antipsychotic or antidepressant drugs and/or aimed at controlling pathogenetic mechanisms, such as inflammation and thrombosis. EULAR recommendations have been published to guide in this process (Bertsias, 2010).

Faced with a patient with possible NPSLE, two issues are critical. First, is it really related to lupus? Many clinical manifestations are vague and can be best explained by alternative hypotheses, such as infection (viral, opportunistic, bacterial, TB), drug toxicity and even fatigue or depression. CNS imaging, cerebrospinal fluid examination and cognitive tests are not always helpful, thereby making the picture even more complicated. Other demyelinating diseases, such as multiple sclerosis, need to be ruled out (Magro Checa, 2013). The second dilemma deals with the mechanism involved: is it inflammation or thrombosis mediated by anti-phospholipid antibodies? Or do both play a role? While this question might look trivial in theory, the answer is always difficult at the bedside. Yet, treatment is very different!

The data currently available, albeit scarce, support the use of IV methylprednisolone and IV CYC pulse therapy as first choice treatment in severe NPSLE, after exclusion of manifestations which could be attributed to the presence of anti-phospholipid antibodies (Trevisani, 2006, Cochrane review). In a retrospective analysis, CYC was found efficacious in treating patients with organic brain disease (55% of the patients in that study), stroke (35%), neuropathies (10%), persistent headache (10%), seizures (9%), psychiatric manifestations (26%), transverse myelitis (16%) and cranial neuropathies (13%). Improvement was observed in 61% of the patients, stabilisation in 29% and deterioration in 10% (Neuwelt, 1995). Only 1 non-blinded randomized controlled trial compared the efficacy of pulse IV methylprednisolone versus IV CYC in treating NPSLE. CYC was administered as monthly pulses (0.75 g/m²) for 6 months and then every 3 months for one year. CYC was significantly more effective in the treatment of NPSLE than pulse IV MP, particularly in treating patients with seizures, optic neuritis, peripheral neuropathy, and brainstem disease (Barile-Fabris, 2005). In acute severe NPSLE, such as transverse myelitis, prompt installation of combined therapy with pulse IV methylprednisolone and IV CYC should be considered strongly.

In refractory NPSLE cases, other treatments can be tried, without strong evidence base. Case reports suggest that PE (Neuwelt, 2003; Bartolucci, 2007), IVIG (Sanna, 2008), RTX (Narvaez, 2011) and even intrathecal dexamethasone and MTX (Zhou, 2008) can be useful.

In patients with SLE and the anti-phospholipid syndrome, the approach should clearly be different, with oral anticoagulation strongly advised to maintain an INR value around 2.5-3 (Ruiz-Irastorza, 2005). The possible role of anti-platelet agents in these patients is under discussion, as is the intensity of anticoagulation (INR) and the duration of therapy. Given the effects of antimalarials on platelet aggregation, HCQ should be considered as well. In Table V, a tentative treatment scheme for NPSLE is proposed.

Table V: Management of NPSLE

Inflammatory mechanisms *	
Induction	Pulse IV MP and IV CYC Symptomatic therapy Plasma exchange in refractory cases Rituximab in refractory cases
Maintenance	GC tapering Steroid-sparing immunosuppressant: AZA, MMF(?) Symptomatic therapy
Thrombotic mechanisms *	
Induction	Oral anticoagulation (target INR 2.5-3.0) Symptomatic therapy
Maintenance	Oral anticoagulant (target INR 2.5-3.0) Symptomatic therapy Low-dose aspirin

** beware that both mechanisms can play a role at the same time*

2.3 Mucocutaneous involvement

Expertise is needed to make a proper distinction between acute, subacute and chronic cutaneous lupus erythematosus (CLE), not to mention lupus profundus, chilblain lupus and lupus tumidus (Okon, 2013). The differential diagnosis is broad: some more common conditions, such as rosacea, need to be ruled out. In patients with cutaneous involvement, photo protection is very important and strict sunscreen adherence and adequate clothing must be emphasised and/or application of a sun protection factor ≥ 50 spf about 20 minutes before sun exposure (Kuhn, 2011a). Topical GCs, topical tacrolimus and antimalarials are first-line therapies. Topical GCs must be prescribed and preference must be given to the potent fluorinated derivatives (instead of hydrocortisone) (Jessop, 2009). They should however be used with “holiday” periods (e. g. two weeks on and one week off) to avoid skin atrophy and telangiectasias. Topical CNIs have been introduced more recently with excellent results reported for tacrolimus ointment (Tzung, 2007; Kuhn, 2011b). Antimalarials are the standard systemic therapy of CLE. HCQ is most frequently used, but in more severe cases of chronic CLE, better results have been reported with chloroquine, quinacrine and with combinations of different antimalarials (Meinao, 1996; Toubi, 2000). When antimalarials fail, MTX has been shown effective in a few RCTs and case series, and AZA, THA and dapsone can be efficacious in difficult to treat cases (Kuhn, 2016). Belimumab showed efficacy in a subgroup analysis of the BLISS trials for mucocutaneous parameters (Manzi, 2012). THA deserves special attention given its impressive effects in refractory chronic CLE (Cortez-Hernandes, 2012), with the caveats already mentioned before. There is one case report of the successful use of tocilizumab (anti-IL 6) in a case of refractory SLE with lupus tumidus and urticarial vasculitis (Makol, 2012). The type I IFN system has also become a potential target in cutaneous disease, since skin lesions are characterized by a strong expression of IFN-regulated proinflammatory cytokines. Anifrolumab showed significant improvement of disease activity including skin lesions, suggesting efficacy in cutaneous lupus (Furie, 2015).

2.4 Musculoskeletal involvement

Non-erosive polyarthritis, affecting predominantly finger joints, wrists and knees, occurs in the vast majority of SLE patients (about 90% of cases) and is one of the earliest disease manifestations. Low-dose GCs and antimalarials are the first choice treatment for polyarthritis, together with NSAIDs in the absence of contraindications. In more severe GC-dependent cases, MTX can be prescribed based on several trials and case series (Gansauge, 1997; Carneiro 1999; Islam, 2012; Rahman 1998; Winzer, 2010), as well as LEF (Remer, 2001; Wu, 2013), AZA or belimumab (BLISS trial). Less frequently, SLE patients develop a deforming arthropathy, called Jaccoud’s arthropathy, which mostly appears insidiously and induces much disability in daily life activities. While the classical acute polyarthritis is usually promptly responsive to therapy, few interventions (including rehabilitation procedures) are helpful in Jaccoud’s arthropathy.

Osteoporosis has long been neglected in SLE, based on the wrong assumption that young women were protected against GC-induced bone loss by their female hormones. SLE patients, however, have an increased risk of osteoporotic fractures (1.2-4.7 fold) compared to the general population and the risk is further increased by a longer disease duration, GC use in the previous 6 months, and previous osteoporotic fractures (Bultink, 2014). Another cohort study detected prevalent vertebral fractures in 18-50% of SLE patients and revealed low 25-hydroxyvitamin D serum levels, low body mass index and baseline use of antimalarials as associated with bone loss in SLE (Bultink, 2016). Smoking, renal and ovarian failure, and reduced exercise are traditional risk factors often encountered in SLE patients. These data show that this comorbidity cannot be neglected and risk factors should be actively assessed and if possible treated, for example by vitamin D3 and calcium supplementation, exercise and smoking cessation. The use of anti-osteoporosis medication in premenopausal women has unfortunately remained poorly studied despite the clear need for data in patients with severe SLE starting at younger ages.

Avascular osteonecrosis (AON) is frequent in SLE, mainly in patients treated with high-dose GCs (Houssiau, 1998) and is a major contributor to musculoskeletal damage, as assessed by the SLICC-DI. The best prevention is to avoid high doses of GCs as much as possible.

2.5 Haematological involvement

Mild leukopenia is frequent when SLE is active and does not require treatment per se. Anaemia is also common in SLE and might be unrelated (iron deficiency being common in women of childbearing age) or linked to the disease, either through chronic inflammation (active SLE commonly induces erythroblastopenia), renal impairment, or haemolysis (much rarer). In case of erythroblastopenia, treatment of lupus usually corrects the anaemia. Active haemolysis (low haptoglobin, elevated LDH, high reticulocyte count) usually requires high dose GCs, promptly tapered, together with a GC-sparing agent, such as AZA or MMF. In relapsing or refractory cases, RTX and recently belimumab have been shown useful. Mild thrombocytopenia, as for example often seen in the presence of antiphospholipid antibodies, does not require specific therapy. Severe thrombocytopenia can be life-threatening and requires high dose GC treatment (pulse IV methylprednisolone and oral prednisolone) and/or IVIG. Again, steroid-sparing agents should be prescribed if remission cannot be maintained with low dose GCs. RTX and splenectomy can be considered in refractory/relapsing cases.

When thrombotic thrombocytopenic purpura (or thrombotic thrombocytopenic microangiopathy) occurs in the setting of pre-existing SLE the syndrome is typically associated with the presence of antiphospholipid antibodies. This diagnosis should always be excluded in a lupus patient with pancytopenia, mainly acute thrombocytopenia, haemolysis, an excess of schistocytes on blood smears, renal failure and other micro-thrombotic manifestations (e. g. skin necrotic lesions). This microangiopathy, sometimes present within the

frame of the so-called “catastrophic antiphospholipid syndrome” requires aggressive therapy combining plasma exchanges, anticoagulants and GCs.

The macrophage-activation haemophagocytic syndrome (Rosado, 2013) is a potentially fatal complication of SLE, mainly in children (Parodi, 2009; Bennet, 2012), and should always be excluded in critically ill patients with fever, pancytopenia, elevated liver enzymes, coagulopathy (hypofibrinogenaemia), elevated ferritinaemia and high triglyceride levels. Bone marrow aspiration shows the typical picture of macrophages phagocytosing haematopoietic cells. The syndrome is a cytokine storm due to unabated macrophage activation. Prompt intervention is required with IV methylprednisolone and oral GC. In severe cases, IV CYC, CYA and cytostatic drugs such as etoposide may be useful adjunct therapies.

2.6 Serositis

The treatment of SLE-related serositis is mostly based on the usual treatment for active SLE. Medium doses of GCs are usually needed. Other immunosuppressants have been used successfully, such as AZA or MTX. Pleuro-pericardiocentesis may be required in case of large effusions or to rule out other diagnoses in difficult cases.

3. COMORBIDITIES

3.1 Cardiovascular disease

In 1976, Urowitz et al. first described a “bimodal mortality pattern” in SLE, with a first peak due to the disease itself and a second wave related to cardiovascular disease (CVD) (Urowitz, 1976). This pivotal observation was largely confirmed by many expert groups and it is now clearly established that SLE patients are at high risk of CVD (Manzi, 1997; Roman, 2003). While traditional factors (smoking, hypertension, diabetes, hyperlipidaemia, etc.) play an obvious role and must be reviewed (Table VI), they do not fully explain the risk, thereby lending support to the possibility that unabated lupus-induced inflammation per se is a risk factor. In this respect, one should expect that GC use would be associated with improved cardiovascular prognosis but the data prove exactly the contrary: prednisone doses of more than 10 mg/day increase the cardiovascular risk two fold and doses of more than 20 mg/day fivefold (Magder, 2012), probably due to the well-known metabolic effects of GCs. Taken together, disease control is essential but this goal should be achieved with the lowest possible cumulative dose of GCs. Antimalarials contribute to a more favourable lipid (Rahman, 1999) and glucose (Petri, 1994) profile and display some antithrombotic activity (Ruiz-Irastorza, 2006), by reducing the binding of antiphospholipid anti-beta2-glycoprotein I complexes to phospholipid bilayers (Rand, 2008). Finally, primary prevention with aspirin and statins should also be considered. In vitro and in vivo studies suggest that statins have direct anti-inflammatory, antithrombotic and plaque-stabilizing effects via a number of mechanisms, besides their well-known lipid-lowering effect. However, a well-designed randomized controlled trial (the LAPS trial) with atorvastatin failed to demonstrate prevention of progression of coronary artery calcium

content and carotid intima thickness in adult SLE patients (Petri, 2011), and therefore it is at present unclear if the use of statins can be advised in the absence of hypercholesterolemia.

Table VI: Cardiovascular risk factors and targets in SLE.

Risk factor	Target	Interventions
Blood pressure	<120 mmHg syst; <80 mmHg diast	ACEI/ARB as first choice
LDL cholesterol	<100 mg/dl or <130 mg/dl	Statins - HCQ
Diabetes mellitus	Fasting blood glucose <7.0 mmol/l	Weight loss – Metformin – HCQ
Smoking	Stop smoking	Nicotine replacement – Bupropion – Varenicline
Obesity	Body mass index <25 kg/m ²	Diet – Aerobic exercise
Homocysteine	<85 µg/dl	Folic acid supplements

3.2 Other comorbidities

Relevant comorbidities and the main preventative measures are shown in Table VII.

Table VII: Comorbidities in SLE.

Comorbidity	Interventions
Cardiovascular disease	See. Table VI
Osteoporosis	Less GCs Calcium salts and D3 supplementation Bisphosphonates in selected cases Exercise Smoking cessation
Infections	Less GCs Anti-influenza immunization (yearly) Anti-pneumococcal immunization (q5 years) Anti-HPV
Vitamin D3 deficiency	D3 supplementation (25-OHD3 ≥25 ng/ml)
Fatigue	Exercise
Malignancy	PAP smears (yearly)
Secondary fibromyalgia	Exercise Pain clinic

Prevention of infections deserves special attention as it is one of the leading causes of death in SLE (Cervera, 2003). Not only opportunistic infections but also common pathogens, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, contribute to mortality. SLE patients must be vaccinated against relevant pathogens (but note that the use of live vaccines may be contraindicated if they take GCs and/or other immunosuppressants). Current data suggest that vaccination of SLE patient is safe and efficacious (Kuruma, 2007; Battafarano, 1998), although serum antibody titers may be lower, but sufficiently protective; older concerns that vaccination could trigger lupus flares have not been born out in carefully designed studies.

4. ADHERENCE TO THERAPY

Not surprisingly, many young lupus patients do not take the many pills we prescribe to treat their L or LN, as recently demonstrated by HCQ blood titers measurements. Some patients take their medications only for a few days before the visit the clinic, a common phenomenon in chronic diseases known as “white coat compliance”. Thus, a hypertensive patient who wants to please his physician will take a few blood pressure-lowering pills for a short period of time preceding the visit and will be declared compliant since his/her blood pressure levels measured the day of the visit will be deemed satisfactory. In contrast, patients taking HCQ once in a while will be unmasked by whole blood HCQ measurements. In a retrospective analysis, more lupus flares were observed in patients who were less compliant (Costedoat-Chalumeau, 2007). Non-adherence can be addressed in clinical practice by repeated explanations given to lupus patients and their relatives on the reasons why each drug is prescribed, and by sketching the global treatment plan as soon as the treatment is started, so that patients understand that many of the drugs will be progressively withdrawn or their dose tapered, even if some will be prescribed for several years. In this respect, the help of a nurse practitioner in our busy lupus clinics can be most valuable.

SUMMARY POINTS

- Glucocorticoids are responsible for some of the damage observed in SLE. Their use should be limited to the shortest possible period of time. Intravenous pulse methylprednisolone therapy is useful for acute life-threatening cases and may allow reduction of peak oral GC dose.
- Antimalarials should be considered for all SLE patients, even in the absence of overt active clinical manifestations. Their benefits include flare prevention, amelioration of some SLE symptoms, and beneficial effects on lipid and glucose profile. They are also believed to have antithrombotic properties and may reduce cardiovascular risk. Antimalarials are safe in pregnancy and need not be discontinued.
- In lupus nephritis, intravenous pulse cyclophosphamide (either the low-dose Euro-Lupus regimen or the higher-dose NIH regime) and mycophenolate mofetil are equivalent induction therapies. Azathioprine and mycophenolate mofetil can both be used for long-term maintenance treatment. Yet, further improvement is eagerly awaited since complete renal remission rate is only 30% after induction therapy and since up to 40% of patients suffer from renal relapse.
- Belimumab is the first biologic approved for the treatment of lupus. It was shown superior to standard of care in two pivotal trials. Yet, its precise place in daily practice needs to be further defined. Other biologic therapies are currently being tested, with promising results for the type-1 interferon inhibitor anifrolumab.
- Despite two negative randomized trials, rituximab deserves further investigation, based on many reports suggesting efficacy in severe refractory cases of lupus nephritis and of some other lupus manifestations. Several trials are currently ongoing under the umbrella of the Lupus Nephritis Trials Network (www.lupusnephritis.org).
- Kidney transplantation is an important option for patients with end-stage renal disease. Recurrence of lupus nephritis after renal transplantation is rare and graft survival is by and large comparable to a control population.
- Patients with SLE are at increased cardiovascular risk. Traditional risk factors should therefore be monitored and controlled by lifestyle modification (*e. g.* diet, weight control, smoking avoidance) and by specific treatments (*e. g.* statins, antihypertensive).
- Patients with SLE, especially those treated with GC and other immunosuppressants, are at high risk of infections. Immunization against influenza and *Streptococcus pneumoniae* is strongly recommended. Osteoporosis is another major comorbidity to evaluate and manage if necessary.
- Lack of adherence to therapy may contribute to treatment failure.

IN-DEPTH DISCUSSION I

**Treatment of systemic lupus erythematosus during
pregnancy**

1. Morbidity and risk factors in lupus pregnancy

Lupus patients run high-risk pregnancies for themselves and their baby, as illustrated by the data gathered in a meta-analysis performed on 37 studies, totalizing 2,751 pregnancies in 1,842 lupus patients (Smyth, 2010). They are summarized in Table I.

Table I: Foetal and maternal morbidity in SLE pregnancy*

Foetal complications (%)		Maternal complications (%)	
Unsuccessful pregnancy	23.4	Lupus flare	25.6
Premature birth <37/40	39.4	Hypertension	16.3
Still birth	3.6	Nephritis	16.1
Neonatal death	2.5	Pre-eclampsia	7.6
Foetal growth retardation	12.7	Eclampsia, stroke and death	<1.0

*: After Smyth, 2010

Several risk factors of poor foetal and maternal outcome have been repeatedly identified (Bramham, 2011; Chakravarty, 2005; Kwok, 2011). They include active maternal disease at the start of pregnancy (and obviously during pregnancy), past history of renal disease, past history of thrombosis, uncontrolled hypertension, smoking and antiphospholipid antibody positivity. Regarding the latter, it was hypothesized that placental thrombosis was the major mechanism leading to foetal loss but this assumption is not confirmed by histological examination of lupus placentas, where thrombosis is rare. Rather, the current view is that antiphospholipid antibodies, actually anti- β 2-glycoprotein 1 antibodies, crosslink β 2-glycoprotein 1 molecules massively anchored to phosphatidylserine flipped to the outer layer of trophoblasts when these cells fuse during syncytium formation. This compromises their proliferation and differentiation and leads to defective placentation (Moroni, 2011). Heparin most likely interferes with this process by inhibiting binding of β 2-glycoprotein 1 to phosphatidylserine.

2. General management of lupus pregnancy

Preconception evaluation is pivotal. It may discourage pregnancy in the few patients with end-stage organ failure, such as a GFR below 30 ml/min/1.73m², pulmonary hypertension, heart or lung failure, etc. More frequently, it will help delaying pregnancy for several months until the disease is fully under control, in order to optimize the success rate. Last, but not least, the medication chart will be discussed in depth in order to decide which drugs should be withheld (and when) and which ones should be continued or introduced.

Pregnant lupus patients should be followed by an experienced multidisciplinary team, ideally within the frame of a Lupus-in-Pregnancy Clinic, where obsessional medical and obstetrical follow-up can be provided. Besides standard clinical examination, the rheumatologist will check the following on monthly interval: serum

creatinine, full blood count, liver tests, urinalysis, proteinuria, serum complement and anti-DNA antibody titres. Of note, not all symptoms presented by lupus pregnant patients should be attributed to lupus! Thus, fatigue, facial blush, hair loss, anaemia, gingivorrhagias, dyspnoea and headaches are all very common in normal pregnancies and should not mislead the clinician. Thyroid tests should be performed at baseline given the high prevalence of autoimmune thyroid disease in SLE. Needless to say, immunization status against several pathogens needs to be checked, like in the normal pregnant population.

Pregnant lupus patients should see an obstetrician as soon as pregnancy is diagnosed in order to determine the age of pregnancy as accurately as possible. Then, monthly visits will be scheduled until week 20, every fortnight until week 28 and weekly thereafter. Between week 16 and 24, special attention will be given to the foetal heart rate in anti-SSA/Ro and/or anti-SSB/La patients (vide infra). Uterine, umbilical and cerebral artery Doppler studies will be performed on a regular basis as foetal surveillance tests. Placentation is best evaluated by uterine Doppler. Thus, the persistence of a protodiastolic Notch after week 26 reflects poor placentation and predicts poor outcome (prematurity, growth retardation). Umbilical Doppler evaluates placental resistance: an absence of end diastolic flow (a fortiori a reverse diastolic flow) after week 24 indicates increased placental resistance and correlates with poor outcome. At last, cerebral artery Doppler evaluates brain vessels vasodilation due to foetal hypoxia (the so-called brain sparing effect): a resistance index below the 10th percentile after week 24 also predicts bad outcome. Serial measurements are of the utmost importance because they help define a prognostic trend and contribute to the decision of elective premature delivery, based on the risk/benefit balance, after having induced foetal lung maturation with fluorinated glucocorticoids that cross the placental barrier.

The differential diagnosis between a renal lupus flare and preeclampsia is always difficult since both conditions cause proteinuria. Arguments in favour of each diagnosis, all relative, are described in Table II. Serum C3 levels are of special interest in this setting (Buyon, 1986). Elevated uric acid levels have been associated with pre-eclampsia rather than lupus (Bellomo, 2012).

Table II: Differential diagnosis between a lupus flare and preeclampsia

	Preeclampsia	Lupus flare
Extra-renal signs	-	+
Haematuria	-	+
Elevated liver tests	+	-
Low platelets	+	±
Microangiopathy	+	-
Elevated serum uric acid	+	-
Low serum complement	-	+
Elevated anti-DNA antibodies	-	+
Response to glucocorticoids	-	+
Response to delivery	+	-

3. Lupus medications

The most important rule is to control the mother's disease. In this respect, patients should be warned against abrupt withdrawal of all therapies, as they could be tempted to do without adequate preconception counselling. Lupus flares need to be adequately treated by non-fluorinated glucocorticoids (GC), which are not harmful to the foetus, as they are likely inactivated in the placenta. While GC, which can also be administered in IV pulse therapy, might be life-saving in critically-ill pregnant SLE patients, a note of caution must be made regarding the use of high doses of oral GC which have been associated with hypertension, diabetes and premature rupture of the membranes (Ostensen, 2006). The only immunosuppressants on the black list in pregnant SLE patients are cyclophosphamide, methotrexate and mycophenolate mofetil, because of their well-known teratogenicity. In very severe and selected cases, they could, however, be prescribed after the first trimester, when most of the organogenesis is done. NSAIDs are clearly contra-indicated, mainly after week 32 (premature closure of ductus arteriosus). Cyclosporine A, hydroxychloroquine and azathioprine (AZA) do not harm the foetus. A recent report indicated that offspring born from mothers treated with AZA run a higher risk of late development delays (Marder, 2013), but these data require confirmation in a larger prospective study.

4. Management of hypertension

Hypertension is common in SLE patients, especially in those suffering from lupus nephritis. Recommendations regarding blood pressure lowering drugs parallel those for the general pregnant population. Thus, ACEI/ARBs must be withdrawn from the second trimester onwards because they can cause ACEI foetopathy (oligohydramnios, renal failure, hypotension and bone malformations). β -blockers may induce foetal bradycardia and intra-uterine growth retardation. Diuretics are not advisable given their effect on placental perfusion related to maternal volume depletion. Treatment of hypertension therefore relies on the use of α -methyldopa, calcium channel blockers, labetalol and hydralazine.

5. Management of the antiphospholipid syndrome in lupus pregnancy

Table III is aimed at guiding physician's choice according to different clinical sketches. Two proposals are evidence-based. First, patients with a history of thrombosis treated with vitamin K antagonist, whether they have – or not – antiphospholipid antibodies (APL Ab), must be switched as soon as possible to full dose heparin or full dose low-molecular weight heparin (LMWH) (sketch #1). Second, patients with antiphospholipid antibodies (APL Ab) and at least one episode of late foetal loss (after week 10) or early eclampsia or severe intrauterine growth retardation, the combination of low-dose aspirin and prophylactic doses of heparin (or likely LMWH) must be prescribed as it was shown to improve foetal outcome (Empson, 2005; Mak, 2010) (sketch #4). The jury is still out whether low-dose aspirin alone is sufficient for patients with recurrent early

foetal losses, with some physicians advising combination therapy upfront, while others will reserve it for low-dose aspirin failures (sketch #3). Whether asymptomatic APL Ab-positive patients should be given low-dose aspirin is also a matter of debate (sketch #1).

Table III: Management of the antiphospholipid syndrome in pregnancy

Sketch	APL Ab	History of			Proposal
		Thrombosis	Recurrent early ($\leq 10/40$) foetal losses	Late foetal loss ($>10/40$) Early preeclampsia	
#1	+/-	+	0	0	LMWH full dose
#2	+	0	0	0	No treatment or low-dose aspirin
#3	+	0	+	0	Low-dose aspirin Combined with LMWH prophylactic in case of aspirin failure
#4	+	0	0	+	Combination of low-dose aspirin and LMWH prophylactic

6. Management of the neonatal lupus syndromes

Neonatal lupus (NNL) is a rare syndrome observed in a very small percentage (2%) of offspring born from mothers with anti-Ro/SSA and/or anti-La/SSB antibodies, who suffer from SLE, Sjögren's syndrome or are asymptomatic antibody carriers (Brucato, 2002). The autoantibodies cross the placenta and may harm the foetus until they disappear from the circulation. The most dire clinical manifestation is a complete congenital heart block (CHB), that usually appears between week 16 and 24 of pregnancy and is fatal in 15 to 30% of cases, with many survivors requiring permanent pacing. Abrupt onset is classical but, in some cases, the complete block is preceded by a lesser degree block. Myocarditis and pericarditis may be associated. The skin might be involved, typically with subacute lesions that disappear after a few weeks or months, very much in contrast to the CHB, which is permanent. Other manifestations of NNL include hepatosplenomegaly, hepatitis, haemolysis and thrombocytopenia. The risk of recurrence (in another child) is high (20%). The only recommendation is to perform serial echocardiograms and obstetric sonograms, at least every 2 weeks starting from week 16 onwards, in mothers with anti-Ro/SSA and or anti-La/SSB antibodies. The goal is to detect early foetal heart abnormalities (*e. g.* premature atrial contractions, signs of congestive heart failure or pericardial effusion), that sometimes precede complete atrioventricular block and may justify therapy with fluorinated GC, that cross the placenta. Routine prophylactic therapy with fluorinated steroids is not recommended even in women who previously gave birth to a child with NN. The hope that IV Ig maternal therapy would lower the risk of recurrence of CHB was turned down by a recent prospective study (Friedman,

2010). By contrast, a retrospective study suggests that HCQ use significantly reduces the recurrence of CHB (21.7% in non-HCQ users *versus* 7.5% in HCQ users) (Izmirly, 2012).

IN-DEPTH DISCUSSION II

**How to translate treatment recommendations into daily
practice**

In the main text of this module, various treatment options and their indications in SLE are discussed. Despite heterogeneity of SLE and the limited number of controlled trials in certain areas, treatment recommendations have been published for lupus (Bertsias, 2008) and lupus nephritis (Bertsias, 2012; Hahn, 2012). The aim of this in-depth discussion is to facilitate the transfer of general treatment recommendations to each individual lupus patient. Treatment should be based on regular assessments of *i*) disease activity, *ii*) damage, *iii*) quality of life (and other patient reported outcomes), *iv*) co-morbidities, and *v*) drug toxicity.

Disease activity assessment should always support treatment decisions at the bedside. Several activity scores (SLEDAI, SLAM, ECLAM, BILAG) have been validated which can be used in clinical practice. Probably the most complex (but also the most comprehensive) instrument is the BILAG index, in which the scoring is based on the principle of physician's intention to treat in 8 organ domains

(<http://etheses.bham.ac.uk/149/1/Yee08PhD.pdf>). Grade A and B flares, which are defined by the requirement for potent immunosuppression, are now used as inclusion criteria in many clinical trials, and the definitions used to characterize these flares, in the 8 organ domains, comprise most of the reasons for intervention in active lupus patients. Therefore, if appropriate teaching is provided, the BILAG scoring system captures a very clear picture of active, controlled or uninvolved organs. While full control of disease activity should be the ultimate goal of immunosuppressive therapy in SLE, persistent complete remission is rarely achieved in the real world (Urowitz, 2005) and tight control of disease activity is only a very recent approach in SLE, very much in contrast to what is already applied for many years in rheumatoid arthritis. A potential risk could be to over-treat lupus patients thus exposing them to unnecessary drug-related side effects. The aim of the recently described treat-to-target approach in SLE is to achieve minimum disease activity over prolonged periods of time without drug-induced morbidity, with the hope to reduce damage accrual (Mosca, 2012), as assessed by the SLICC damage index (Gladman, 2000).

Besides regular evaluations of disease activity and damage, more attention should be paid to quality of life (QoL). This outcome measure is obviously the most important from a lupus patient's perspective and is becoming increasingly relevant, thanks to improved survival rates and due to the growing need for more clinically- and scientifically-based arguments to justify the reimbursement of expensive drugs, such as biologics. Patients with SLE generally perceive their health as being suboptimal, with 35–50% of patients rating their health as 'fair/not so good' or 'poor' (Zink, 2004; Fischer-Betz, 2005; Yelin, 2007; Katz, 2009). All subscales of the SF-36, a universal instrument to evaluate QoL, are impaired in comparison to healthy controls (Barta, 2010). The level of health-related QoL is only partially explained by disease activity and damage. Across all studies, the most commonly implicated factors impairing the QoL of SLE patients are older age, fatigue and the coexistence of neurological or psychiatric disorders (especially depression and anxiety) (Schmeding, 2013). Fatigue is clearly a major issue, even in patients with fully controlled disease. Reasons for fatigue are manifold: anaemia, decreased vitamin D levels, disease activity, secondary fibromyalgia, depression, sleep disturbance,

lack of aerobic fitness and, most frequently, combination of all those. Lupus patients, like patients with other chronic illnesses, experience a vicious circle starting with disability, pain and fatigue caused by active disease, which is accompanied by depression and leads to inactivity. As a consequence, patients further limit their physical activities, thereby further reducing their aerobic capacity and further increasing their fatigue and disability. In addition to its direct effect on QoL, reduced physical activity favours premature atheroma and its cardiovascular consequences. Taken together, QoL should be in the focus of every visit. When disease activity is under control, patients should be advised to perform supervised exercises. There is only limited evidence that exercise improves fatigue in lupus patients but the data available so far at least document that physical training is safe in patients with mild disease activity and that many patients experience QoL improvement. This said, a direct start with exercise may be too high a hurdle for some heavily fatigued patients who will feel even more exhausted after training. For them, and also for those with overt depression, a psycho-educative training may be indicated as first approach (Haupt, 2005). It is of critical importance that patients switch from a passive to a more active coping strategy. In special cases, antidepressants may be indicated.

Pregnancy related problems in rheumatic diseases, including the antiphospholipid syndrome

Rebecca Fischer-Betz, Magdalena Siekierka-Harreis, Nathalie Costedoat-Chalumeau

A previous version was coauthored by Gaëlle Guettrot-Imbert, Nathalie Costedoat-Chalumeau, Angela Tincani

Part I: pregnancy and rheumatic disease

LEARNING OBJECTIVES

- Recognise and evaluate specific maternal and foetal problems arising in different rheumatic diseases during pregnancy
- Recognise periods during and after pregnancy prone to a disease flare
- Perform a risk assessment in each woman planning a pregnancy
- Use an algorithm for treatment in patients planning a pregnancy
- Monitor and follow-up pregnant patients
- Explain the importance of an interdisciplinary approach in the follow-up of pregnant patients
- Counsel women with rheumatic disease desiring children

1. Introduction

Rheumatic diseases occur preferentially in women, often during child-bearing age. Most women with rheumatic disease wish to have children even when functional disability is present. Pregnancies in these women are now common. The interaction of pregnancy and the rheumatic diseases is varied, ranging from spontaneous improvement to aggravation of disease symptoms. Likewise, rheumatic diseases differ in the occurrence of complications during pregnancy and pregnancy outcome (table 1). This chapter describes the maternal course of several common and some rare rheumatic diseases during pregnancy, foetal outcome and treatment during pregnancy and post-partum. The antiphospholipid syndrome (APS) is described in part 2 of this chapter.

Table 1 Influence of pregnancy on the course of several rheumatic diseases and on foetal/neonatal outcome

Disease	Risk of major organ involvement during pregnancy	Increased risk of foetal/neonatal complications	Prevailing response of disease to pregnancy
Rheumatoid arthritis	Rare	Prematurity and IUGR increased in presence of active RA NLS	Improvement in about half of the patients
Ankylosing spondylitis	No	Prematurity	Active/aggravated
Juvenile idiopathic arthritis	No	No	Improvement
Connective tissue diseases†	Organ involvement not more frequent than outside pregnancy	Prematurity, IUGR, NLS	No major influence or variable
Systemic lupus erythematosus	Possible, especially renal involvement	Pregnancy loss, IUGR, prematurity, NLS	Active/aggravated
Antiphospholipid syndrome	No	Pregnancy loss, IUGR, prematurity	Higher risk of thrombosis especially in the peripartum period
Vasculitis	Respiratory tract, kidney	Foetal loss, prematurity, IUGR	Too few data to discern a major effect

†Sjögren's syndrome, systemic sclerosis, dermatomyositis/polymyositis.

NLS, neonatal lupus syndrome; RA, rheumatoid arthritis; IUGR : intrauterine growth restriction.

2. Specific terminology in pregnancy

2.1 Pre-eclampsia

According to the American College of Obstetrics and Gynaecology guidelines, the diagnosis of pre-eclampsia no longer requires the detection of proteinuria. Pre-eclampsia can be defined by the association of (1) persistent high blood pressure that develops during pregnancy or during the postpartum period (blood pressure >140 mm Hg systolic and/or >90 mm Hg diastolic in two separate readings taken at least 6 h apart), and (2) one of the following: proteinuria, low platelets, kidney or liver involvement, fluid in the lungs, seizures and/or visual disturbances.

2.2 HELLP syndrome

The diagnostic criteria used for the Haemolysis, Elevated Liver, Low Platelets (HELLP) syndrome are variable and inconsistent. Haemolysis defined as the presence of microangiopathic haemolytic anaemia, is the hallmark of the triad of HELLP syndrome. The classic findings of microangiopathic haemolysis include abnormal peripheral smear (schistocytes), raised indirect bilirubin, low haptoglobin levels, raised lactate dehydrogenase levels (threshold of 180–600 U/L) and significant drop in haemoglobin levels (Sibai, 2004).

2.3 Intrauterine growth restriction

Small gestational age (SGA) fetuses are those who are smaller than normal for gestational age. SGA can be associated with intrauterine growth restriction (IUGR) and occurs when the unborn baby is at or below the 10th weight centile for his or her gestational age because of pathological conditions.

2.4 Foetal loss in APS

In APS, foetal losses after 10 weeks of gestation are called foetal deaths, whereas in obstetrics, these foetal losses are still called miscarriages (early, or late when they occur after the first trimester).

3. Physiological changes during pregnancy

Multiple adaptations occur during normal pregnancy to allow for tolerance of an immunogenic allograft (the foetus). These adaptations include hormonal and cytokines changes during pregnancy. This is developed in the subsection 1.4 .

Pregnancy-induced hypercoagulability is also a physiological adaptive mechanism resulting in a higher risk of thrombosis, in particular during the third trimester and the six postpartum weeks. Concentrations of coagulation factors II, V, VII, VIII, X and von Willebrand factor rise significantly, accompanied by an increase in the concentration of plasma fibrinogen. Total protein S and activated protein C sensitivity decrease during gestation, whereas protein C levels are unaffected.

White blood cells, mainly neutrophils, erythrocyte sedimentation rate, D-dimers, C3 and C4 levels and CH50 activity physiologically increase during gestation.

Plasma and blood volumes slowly increase by 40–50% over the course of the pregnancy. Consequently, the haematocrit and haemoglobin levels decrease.

Heart rate and cardiac output also increase with a decrease in blood pressure. The glomerular filtration rate commonly increases by 50% with a fall in serum creatinine and urea levels. Proteinuria is increased owing to increased excretion, and levels of up to 300 mg/24 h are considered within the normal range in pregnancy (Germain and Nelson-Piercy, 2006).

4. Immunology of pregnancy

Conception induces a variety of hormonal changes in the maternal body which are necessary for the support of pregnancy and foetal survival. With advancing gestation a complex interplay between the maternal neuroendocrine system, the placenta and the foetus occurs. Circulating plasma levels of bound and unbound cortisol and sex hormones (oestrogens and progesterone) rise progressively during pregnancy. In addition to hormones, immunoregulatory factors are secreted by the placenta that suppress T cell proliferation and

induce tolerance or hyporesponsiveness in maternal T cells. The total number of T and B cells in the maternal circulation remains stable throughout pregnancy, though the composition of T cell subsets changes, especially regulatory T cells, which are a unique subset of suppressive CD4 T helper cells indispensable for immune tolerance to self-antigens and foreign antigens. They also are involved in the maintenance of tolerance and prevent the immunological rejection of the foetus during pregnancy. It has been reported that murine and human pregnancy is associated with an expansion of peripheral blood Treg cell pool compared with a non-pregnant woman, spiking in the second trimester. Thereafter the Treg number decreases to slightly above normal levels at delivery, which provides a partial explanation for the flares following birth.

Pregnancy does not result in a general state of impaired immunity. The maternal defence mechanisms remain intact with normal responses to active and passive immunisation but hyporesponsiveness or tolerance to foetal antigens.

4.1 Cytokines and the Th1/Th2 immune response

Successful pregnancy requires appropriate temporal expression of cytokine and cytokine receptor genes in the decidua and in the maternal circulation. Early studies in mice showed a shift of a Th1 to a Th2 immune response, where it also became evident that successful pregnancy was largely dependent on a Th2 cytokine profile whereas spontaneous abortion showed a Th1 cytokine pattern. Evidence for this shift of the Th response is strongest at the maternal–foetal interface. However, extended studies in animals and humans showed that a modulation adapted to the stage of pregnancy takes place, not a persistent domination of a Th2 cytokine pattern throughout pregnancy. Studies of maternal serum levels of cytokines and their receptors have shown an increase of anti-inflammatory cytokines which can induce tolerance. The increase of regulatory T cells during pregnancy suppresses the proliferation of interferon γ and interleukin 12 (IL-12)-producing effector T cells, and promotes the secretion of IL-10, IL-4 and transforming growth factor β .

4.2 Cellular communication between mother and foetus

Human leucocyte antigen (HLA) incompatibility between mother and child may be an advantage in pregnancy. Foetal cells and cell-free DNA routinely traffic into the maternal circulation during normal pregnancy. The concentration of foetal DNA increases over the course of pregnancy and decreases rapidly after parturition. Studies investigating the response of maternal peripheral blood mononuclear cells to trophoblast or paternal HLA antigens showed that paternal antigens stimulated the production of IL-4 thereby promoting a Th2 response.

4.3 Postpartum period

After delivery, the body readjusts to the non-pregnant state. At the same time, lactation creates a unique hormonal milieu. Thus, the postpartum period is not simply a reversal to the state before conception, but is a

state of its own. Some gestational changes, such as levels of glucocorticoids, reverse quickly, while others, such as lymphocyte subsets and their responses, readjust over weeks and months. As a consequence of decreasing cortisol, catecholamines and other factors, secretion of proinflammatory cytokines increases after delivery. Immunological rebound effects occur as shown by more vigorous B cell responses post-partum. Overall, post-partum is a vulnerable period with a risk of first onset or relapse of autoimmune disease.

5. Fertility

Rheumatic diseases can impair fertility (ability to have a child) and, more often, fecundity (time to achieving pregnancy) in several ways. Pain and stiffness in joints and muscles or involvement of connective tissue of the genital tract, as in systemic sclerosis (SSc), can make sexual intercourse difficult and reduce its frequency. In addition, fatigue, depression and some drugs such as methotrexate may decrease libido. Some patients do not wish to become pregnant out of fear of genetic transmission of their disease. Several autoantibodies can inhibit fertilization or implantation as in the APS. Some connective tissue diseases, like systemic lupus erythematosus (SLE) and APS, can be associated with increased pregnancy loss, which could reduce family size. In addition, chronic disease often disturbs the hypothalamic–gonadal axis and the hormonal balance, resulting in periods of hypogonadism. Thus, complex interactions exist between disease, sexual functioning and fertility. Few drugs are gonadotoxic like the alkylating agents, but treatment with potentially foetotoxic drugs can exclude pregnancy and thereby induce, at least temporarily, infertility. Non-steroidal anti-inflammatory drugs (NSAIDs) can delay or inhibit ovulation due to the inhibition of prostaglandins (Edelman et al, 2013). Recent studies on animal models have suggested that the effect of COX-2 inhibition on the ovary may be strong enough to inhibit ovulation, going as far as to test its potential usefulness as an emergency contraceptive. In one study, the rate of ovulation decreased to 25% in women treated with NSAIDs around the time of ovulation. In another study, ovulation was delayed by a mean of 5 days in women treated with NSAIDs (Bata et al, 2006). This should be kept in mind when attempts to become pregnant fail in a patient receiving treatment.

5.1 Fertility in different rheumatic diseases

In a population-based study, a lower number of births and a reduced period of reproduction were found in women with rheumatic disease compared with healthy controls. The interval between pregnancies was longer and the proportion of women achieving a subsequent pregnancy was reduced in rheumatic disease. Lower birth rates have been reported in women with rheumatoid arthritis (RA), and reflect, at least in part, the choice of these women to limit their family size. This may be due to the experience of parenting disability, particularly in patients with a postpartum flare of RA.

A large retrospective study of reproductive performance in Caucasian patients with ankylosing spondylitis (AS) found on average 2.4 children per woman, which is no different from the fertility rate in the healthy population. A population-based study of women aged 40–42 years found normal fertility but diminished

fecundity in women with AS. Diminished fecundity was also reported in women with juvenile spondyloarthritis, and fertility was found to be reduced compared with the national average. Reduced family size in spite of normal fertility and fecundity can be a result of pregnancy loss due either to miscarriage or stillbirth, or to perinatal deaths but not only this: pregnancy usually has to be planned during periods of disease control, especially in SLE. So, these women have their first child later and fewer children. Pregnancy loss is particularly obvious in patients with APS, and to a lesser degree in women with SLE. An increased rate of pregnancy loss is also seen in patients with familial Mediterranean fever (FMF), active vasculitis or inflammatory myopathies.

6. Rheumatoid arthritis, juvenile idiopathic arthritis, and psoriatic arthritis

6.1 Effect of pregnancy on disease activity in women with RA

Among the rheumatic diseases, the interaction between pregnancy and RA is the most thoroughly studied.

Retrospective studies between 1940 and 1980, comprising a total of 345 pregnancies, indicated that about 75% (range 54–86%) of patients experienced improvement of symptoms and signs of RA during pregnancy (Ostensen *et al*, 2011*). Five detailed prospective studies comprising 128 pregnancies found improvement or remission of RA in about two-thirds. However, the two largest prospective studies found improvement in 65% and 48%, respectively, and complete remission limited to a small proportion of pregnant patients with RA. The difference in gestational improvement is due to the design of early studies, which were mostly retrospective, and lack of appropriate disease activity measurements. The influence of pregnancy on the activity of RA was often judged by global statements of patients. In contrast, more recent studies were preferentially prospective, and used validated instruments to measure disease activity (Ostensen *et al*, 2004; Gromnica-Ihle *et al*, 2006; de Man *et al*, 2008*) (figure 1). In addition, the self-assessment of patients has changed during the past 50 years. In the 1940s only aspirin and gold therapy were available for the treatment of arthritis. Therefore, a beneficial effect of pregnancy was felt as being much more impressive than during a time where highly efficient treatments for RA keep most patients at a low or moderate level of disease activity. Patients who enter pregnancy in a state of low disease activity notice fewer of the beneficial effects of pregnancy, but remain mostly stable. Patients with high disease activity at conception benefit the most from pregnancy. Interestingly, patients negative for both rheumatoid factor (RF) and cyclic citrullinated autoantibodies (CCP) were more likely to improve during pregnancy. In a prospective study of 118 patients, 75% of patients negative for RF and CCP antibodies improved compared with only 39% of those positive for RF and CCP antibodies (de Man *et al*, 2010). In addition, disease severity in early pregnancy is predictive of preterm delivery and SGA (Bharti *et al*, 2015). Most studies agree that if a woman with RA improves during one pregnancy she is likely to do so also in subsequent pregnancies. However, a prospective study reported that RA disease course in following pregnancies could not be predicted based upon previous pregnancies (Ince-Askan *et al*, 2016). Only

15 % of patients had a comparable disease activity course in subsequent pregnancies. In contrast, a flare post-partum seems to predict flares after subsequent pregnancies.

Figure 1 The Rheumatoid Arthritis Disease Activity Index (RADAI) in patients with rheumatoid arthritis with improvement studied prospectively before, during and after pregnancy. pp, post-partum. (Reproduced with permission from Gromnica-Ihle and Østensen, *Z Rheumatol* 2006;65:209–12.)

6.2 Effect of RA on pregnancy outcome

Women with rheumatic diseases in general have been found to have higher risks of adverse outcomes like pre-eclampsia, preterm delivery, caesarean section, foetal death and IUGR or SGA babies. A Norwegian population-based study found the rate of preterm delivery and infants SGA higher for first born children in mothers with RA than in healthy women. Two prospective studies of 285 pregnancies in women with RA found birth weight within normal range, but lower than in healthy women, and even lower in infants of RA mothers with high disease activity or those treated with prednisone.

6.3 Maternal disease activity post-partum

According to retrospective and prospective studies, most patients had recurrent disease within 3–4 months of delivery (Østensen *et al*, 2012*). Prospective studies from the past two decades found that RA relapsed in 49–62% of patients within the first 6 months after delivery requiring an increase in drug treatment. A prospective study showed that entering pregnancy with low disease activity was a relevant factor for stable low disease activity during gestation and even for a reduced risk for a post-partum flare. One study reported a correlation between lactation and increased disease activity post-partum in women with RA, who were breast feeding for

the first time. However, earlier studies reported no correlation between a disease flare and breast feeding. A prospective study evaluating women with a 12-year follow-up found no significant influence of pregnancy on long-term RA outcome, but found a trend for patients with multiple pregnancies to have less radiographic joint damage and a better functional level.

6.4 Pregnancy-induced amelioration and postpartum relapse of RA

A number of different factors have been considered in the pregnancy-induced amelioration of RA. Most of the candidate factors studied, such as increased serum cortisol concentrations, raised levels of sex hormones and pregnancy-associated α_2 globulin, did not explain the improvement of RA during pregnancy. Others, such as reversal of abnormalities in the percentage of IgG immunoglobulins lacking the terminal galactose, have been described in association with amelioration of RA during pregnancy. It has been proposed that prolactin plays a role in the postpartum relapse (Ostensen and Villiger, 2002).

In studies of mother–child pairs for whom the mother experienced RA improvement during pregnancy compared with those who did not, foetal–maternal disparity in the HLA class II molecules HLA-DR and DQ was seen significantly more often in the former than in the latter. One subsequent study confirmed this observation, while another report came to a different conclusion. A study investigating dynamic changes in levels of foetal DNA in serum from women with RA and inflammatory arthritis, during and after pregnancy, found an inverse relationship between serum foetal DNA levels and disease activity. The uptake and cross-presentation of soluble foetal paternally inherited HLA peptides by maternal antigen-presenting cells might well affect autoimmunity in patients with RA, though the nature of this modulation has as yet not been elucidated. Alternatively, or additionally, regulatory T cells might be contributory, increasing during pregnancy and suppressing maternal autoimmune responses. These possibilities are not exclusive and it is likely that the explanation for disease amelioration in RA is multifactorial (Ostensen *et al*, 2012*).

6.5 Juvenile idiopathic arthritis

Some 150 pregnancies have been studied retrospectively in women with a history of juvenile idiopathic arthritis (JIA). Taken together these studies showed a beneficial effect of pregnancy on the activity of oligoarticular and polyarticular JIA, whereas women with juvenile spondyloarthritis most often experienced an aggravation. Most importantly, inactive JIA before conception was not reactivated during pregnancy.

The limited experience from the literature indicates no increase in the rate of miscarriage, pre-eclampsia or premature delivery in women with JIA except in a recent Australian study of two large population health datasets that found a higher rates of pre-eclampsia (that might be related to the use of steroids), postpartum haemorrhage and severe maternal morbidity in women with JIA (Chen *et al*, 2013). Most patients, particularly those with inactive JIA in adulthood, will have uneventful pregnancies and deliver healthy children of normal

birth weight. Compared with other infants, the Australian database showed increased risk of prematurity in children with mothers with JIA but no others adverse neonatal outcomes (Chen *et al*, 2013). A postpartum flare has been described in 52–90% of JIA pregnancies within the year after delivery. Flares are more frequent in women who had active disease before pregnancy and in women who are breast feeding (Ostensen, 1992*).

6.6 Special problems

Problems at delivery may arise in women with early-onset JIA due to growth disturbances. If the maternal bone alteration has affected the pelvis, cephalopelvic dystocia can preclude normal vaginal delivery and require caesarean section. Bilateral hip involvement with marked reduction of mobility may also prevent vaginal delivery. Some patients have received hip replacement in adolescence because of severe arthritis in the hip joints. Unilateral or bilateral hip joint prosthesis allows vaginal delivery provided that the range of motion is normal or only slightly reduced. In one study, an increased rate of surgical delivery was found in patients with JIA, mostly in women with hip prostheses. General anaesthesia with intubation may be difficult in patients with temporomandibular or crico-arythenoid joint involvement or in those with subluxation in the cervical spine. Regional anaesthesia is the preferable method in these cases.

6.7 Psoriatic arthritis

The few reports on the interaction between pregnancy and psoriatic arthritis (PsA) comprise 25 pregnancies; 85% of the pregnant patients with oligo- or polyarticular PsA improved during pregnancy. Pregnancy had little effect on skin disease. A postpartum relapse occurred 2–12 weeks after delivery in 60–80% of patients. Except for one stillbirth, no spontaneous abortion or premature delivery occurred in this limited number of PsA pregnancies (Ostensen, 1992*).

7. Ankylosing spondylitis

Both retrospective and prospective studies have investigated the effect of pregnancy on the course and severity of AS. In contrast to RA, pregnancy does not improve the symptoms of AS. In the majority of patients, disease activity is not substantially altered during pregnancy (Lui *et al*, 2011). Two prospective studies involving 32 patients with AS assessed the disease course of AS during and after pregnancy, in detail, by clinical and laboratory measurements. The typical pattern was active disease during the first and early second trimester, sometimes accompanied by a flare around week 20 of pregnancy (figure 2). Active AS produced increased pain and stiffness of the spine, intensified nocturnal pain and occasionally, acute arthritis in the peripheral joints. Pregnancy modifies posture and spinal mobility (by production of relaxin and other hormonal changes during gestation, which cause ligament relaxation). In some patients, pain at the attachment sites of ligaments or tendons and a feeling of tightness in the chest created additional problems. Anterior uveitis could become active during this period. A need for NSAIDs and analgesics was present in about 70% of the patients.

For the group as a whole, disease activity decreased again in the third trimester, but complete subsidence of symptoms was not seen (Ostensen et al, 2012*). Within a population-based case-control study, offspring of women with AS were more often preterm (9.0% vs 4.9%)(Jakobsson et al, 2016). Cases with more extensive antirheumatic therapy exposures tended to have a higher risk for elective caesarean section and being SGA.

Figure 2 The Bath Ankylosing Spondylitis Activity Index (BASDAI) in patients with ankylosing spondylitis studied prospectively before, during and after pregnancy. pp, post-partum. (Reproduced with permission from Gromnica-Ihle and Ostensen, Z Rheumatol 2006;65:209–12.)

Some 20% of patients with AS have improved spinal and extraspinal symptoms during pregnancy. These patients most often have a history of arthritis in joints other than the spine, or psoriasis or inflammatory bowel disease associated with their AS. In patients studied during multiple pregnancies, the intensity of disease symptoms varied from one pregnancy to the other. No uniform pattern of improvement or aggravation emerged. However, complete remission of symptoms never occurred in any patient with pure spinal disease.

7.1 Maternal disease activity post-partum

Fifty percent to 80% of patients with AS experience aggravation of symptoms 4–12 weeks after delivery. Episodes of acute peripheral arthritis or anterior uveitis occur 1.5–3 times more often after delivery than during pregnancy. Disease activity returns as a rule to the pattern before pregnancy during the year following delivery.

7.2 Course of pregnancy and delivery

The rate of miscarriage, foetal death, prematurity and infants SGA is within the limits of the rate for healthy women. As a rule, pregnancies conclude at term with the delivery of live, healthy children of normal birth

weight. Compared with healthy women, Caesarean section is more often performed in patients with AS. Inflammation or ankylosis of the sacroiliac joints is not a mechanical hindrance to the progression of parturition. Also, hip disease or total hip replacements resulting from early-onset AS does not preclude normal delivery.

7.3 Special problems

Anaesthesiologists often fear that neuraxial anaesthesia is difficult to establish in patients with AS because of ankylosis in the lumbar spine. However, ankylosis of the lumbar spine is rare in female patients with AS and occurs only after disease duration of three to four decades. These concerns can be overcome by documenting the absence or presence of ankylosis by carrying out an X-ray examination of the lumbar spine before a planned pregnancy.

8. Systemic lupus erythematosus

Pregnancy in women with SLE is associated with higher maternal and foetal risk than in healthy women. Even if pregnancies are now frequent in women with SLE, they are still associated with higher foetal and maternal morbidity and mortality. The main complications are SLE flares, adverse obstetric outcomes (sometimes due to the associated APS) and neonatal lupus syndrome.

Optimal management requires detailed planning of the pregnancy in a preconceptional consultation, and multidisciplinary care with close collaboration between internist/rheumatologist, obstetrician and anaesthetist (see online in-depth discussion I).

8.1 The effect of disease activity

Active disease during the 6 months before conception and a history of lupus nephritis significantly increase the risk of flares during pregnancy. Flare rates vary between 25% and 65% in the oldest studies (when hydroxychloroquine was stopped). Most of the flares in pregnancy are mild to moderate. They occur as frequently in each trimester, including in the postpartum period (Clowse *et al*, 2005*).

Whereas articular manifestations are less frequent during pregnancy, renal and haematological manifestations are more frequent and more severe during this period. The risk of flares (especially renal) and of maternal and foetal complications (increased rates of perinatal mortality, preterm delivery and foetal growth restriction) depends on lupus activity before conception and on whether kidney damage has occurred (Clowse *et al*, 2005*; Bramham *et al*, 2011). Impairment of renal function may be increased by pregnancy in women with pre-existing kidney disease, especially if there is chronic renal insufficiency, proteinuria, low complement level or hypertension (Bramham *et al*, 2011). Chronic renal insufficiency is associated with higher rates of foetal

loss, foetal growth restriction (Gladman *et al*, 2010) and prematurity (Bramham *et al*, 2011)**Erreur ! Source du renvoi introuvable.**

The PROMISSE study (Predictors of Pregnancy Outcome: Biomarkers in APS and SLE) included pregnant patients with inactive or stable mild/moderate SLE (Buyon *et al*, 2015*). Within these pregnancies, severe flares occurred in less than 5 % of pregnancies. Adverse pregnancy outcomes (APOs) occurred in 19 % of all pregnancies. Baseline predictors of APOs included presence of lupus anticoagulant, antihypertensive use low platelet counts and higher disease activity whereas non-Hispanic white race was protective. Among women without baseline risk factors, the APO rate was 7.8%. For those who either were LAC-positive or were LAC-negative but non-white or Hispanic and using antihypertensives, the APO rate was 58.0% and foetal or neonatal mortality was 22.0%.

8.2. Pregnancy in patients with Lupus nephritis

SLE patients with nephritis are at higher risk for adverse pregnancy outcomes, including premature delivery, low birth weight and intra-uterine growth restriction. According to the EULAR recommendations, pregnancy may be planned in patients with inactive lupus nephritis and UPCR <50 mg/mmol for the preceding 6 months, with GFR that should preferably be >50 ml/min (Bertsias GK *et al*, 2012*). Stable renal disease is treated with the same drugs that are recommended as acceptable during prepregnancy counselling (hydroxychloroquine, prednisone, azathioprine or calcineurin inhibitors). Replacing mycophenolate mofetil with azathioprine in patients with stable lupus and quiescent lupus nephritis for pregnancy planning rarely leads to renal flares (Fischer-Betz R *et al*, 2013*). Low dose Aspirin (LDA) should be started within early pregnancy to reduce the risk for preeclampsia. Patients with nephrotic-range proteinuria during pregnancy are candidates for anticoagulation.

Hypertensive disorders of pregnancy are among the leading preventable contributors of maternal and foetal adverse outcomes, including maternal and foetal death. New onset of hypertension in pregnancy may be a first sign of emerging pre-eclampsia or of renal flare. Arterial hypertension is defined as a blood pressure equal to or higher than 140/90 mmHg in 2 measurements with a time interval of at least 4-6 hours between both. The four types of hypertension during pregnancy are: (1) gestational hypertension, (2) preeclampsia-eclampsia, (3) chronic hypertension, and (4) chronic hypertension with superimposed preeclampsia.

In pregnancy, blood pressure higher than 160/110 mmHg requires immediate treatment. There is no strict definition of a definitive blood pressure goal. Due to the danger of foetal growth restriction with too low blood pressure counts, diastolic blood pressure should not be lower than 90-100 mmHg, or 80-90 mmHg respectively, if the mother has hypertensive end-stage organ damage or other risk factors. Angiotensin-converting enzyme (ACE) inhibitors should be stopped before conception or at the latest in the first trimester. If necessary, an alternative antihypertensive compatible with pregnancy should be given (like Methyldopa,

Labetalol, Metoprolol, Nifedipine). For monitoring, any fall in serum C3/C4 is significant given than levels usually rise during pregnancy. Additional investigations may be needed to rule out pre-eclampsia before diagnosing exacerbation of renal disease.

8.3 Presence of anti-SSA/Ro and/or anti-SSB/La antibodies and risk of neonatal lupus syndrome

Occurrence of neonatal lupus syndrome is related to the presence of anti-SSA/Ro and anti-SSB/La antibodies in mothers with different rheumatic diseases (Sjögren's syndrome, SLE or more rarely, RA), but it also occurs in mothers without any connective tissue disease. These maternal antibodies cross the placental barrier and can cause neonatal lupus in the foetus or newborn, by a passively acquired autoimmunity model, manifesting mainly as cardiac manifestations that are usually permanent or transient cutaneous (figure 3), haematological and/or hepatic manifestations.

Figure 3: Cutaneous lesions of neonatal lupus syndrome on the periorbital region in a 3 month-old child.

Atrioventricular block (AVB) is the most common manifestation of cardiac neonatal lupus. The risk of AVB increases from 1% to 2% in the absence of any history of previous AVB (whereas the estimated incidence of AVB in the population is 0.005%) to around 17% when siblings are born with neonatal lupus (Costedoat-Chalumeau *et al*, 2004*). AVB is most often discovered between 20 and 24 weeks of gestation. The probability of survival to the age of 10 years is 86% in live born children, and pacemakers are required in 70% of them (Izmirly *et al*, 2011*).

Late-onset cardiomyopathy has also been described in children from mothers with anti-SSA antibodies despite early pacing (Moak *et al*, 2001), justifying close follow-up of children with any cardiac manifestation. Cardiomyopathy could be a sequelae of endocardial fibro elastosis, another manifestation of heart toxicity of these antibodies, which can be seen on foetal echocardiography as hyperechogenic heart areas (Nield *et al*, 2002; Guettrot-Imbert *et al*, 2011).

Curative treatment of AVB is based on fluorinated glucocorticoids (betamethasone or, if not available, dexamethasone) that cross the placental barrier, unlike prednisone and methylprednisolone but the value of this treatment is controversial. Complete AV block, once established, seems not to be reversible. No prophylactic treatment is indicated for women with anti-SSA antibodies and an unremarkable history. Hydroxychloroquine seems to reduce the risk of recurrence in another child (Izmirly *et al*, 2012), but further prospective studies are needed to confirm these findings. Hypothyroidism in mothers with anti-Ro/SSA and/or anti-La/SSB antibodies increases by nine fold the risk of delivering a child with congenital heart block compared with women with these same antibodies who have normal thyroid function.

8.4 Effect of antiphospholipid antibodies or APS

See online in-depth discussion II.

8.5 Treatment of SLE during pregnancy

Treatment of lupus during pregnancy usually includes maintenance of the previous treatment, especially hydroxychloroquine. Discontinuation of hydroxychloroquine is related to an increased risk for SLE exacerbations during pregnancy (Andreoli *et al*, 2017). Exposure to prednisone should be limited to <10 mg/day (in the absence of flare). If an immunosuppressive agent is required, azathioprine is preferably used. Uncontrolled studies also suggest an acceptable benefit/risk ratio of calcineurin inhibitors (cyclosporine A, tacrolimus) in controlling SLE activity during pregnancy. Low-dose aspirin is indicated at least in patients with antiphospholipid antibodies, nephritis or a previous adverse obstetrical outcome, and some physicians prescribe this treatment to all patients with SLE to prevent pre-eclampsia (Schramm *et al*, 2014). All pregnant women with SLE, especially those receiving glucocorticoids and heparin, should receive calcium and vitamin D until the end of lactation. Multidisciplinary monitoring includes regular clinical, laboratory and ultrasound evaluations. Delivery may be scheduled at around 38 weeks, but this remains empirical and should be evaluated.

9. Primary Sjögren's syndrome

Primary Sjögren's syndrome (pSS) is 10 times more common in women than in men, with a peak incidence at or near menopause. Most patients with pSS have completed their families before disease onset. Therefore few studies have investigated pregnancy outcome in pSS.

9.1 pSS during pregnancy and pregnancy outcome

Only one study has examined the effect of pregnancy on the symptoms of SS and found no major changes. Thus patients with SS should not expect improvement of sicca symptoms during pregnancy. In previous retrospective studies of patients with pSS the foetal loss rate has varied from 7% to 24%, with a significantly increased risk documented in two studies. In addition to the risk of AVB, a recent case–control study (34 pregnancies) showed a statistically significant increase of the rate of spontaneous abortions, preterm deliveries, low birth weight infants and caesarean section (De Carolis *et al*, 2014). By contrast, two previous studies, involving 172 pregnancies in women with pSS, found neither increase in prematurity or growth restriction nor any influence of anti-SSA and anti-SSB antibodies on the outcome of pregnancy.

9.2 Conclusion

The few reported pregnancies after disease onset do not permit a conclusion to be drawn about the possible influence of established pSS on pregnancy outcome. The most important, though small (1–2%), risk associated with pSS is the development of chronic heart block in children of anti-SSA- or anti-SSB-positive mothers.

10. Systemic sclerosis

SSc has a female preponderance of about 8–10:1 in the reproductive years; the mean age at onset of symptoms is in the early 40s, leaving the possibility of becoming pregnant after onset of the disease. Because of similarity to chronic graft-versus-host disease, the role of transfer of foetal cells during pregnancy and microchimerism was intensively studied in SSc. Microchimeric cells have been demonstrated in the peripheral blood and affected skin of patients with SSc; however, there is no evidence that pregnancy has a decisive role in the aetiology of SSc.

10.1 SSc during pregnancy and pregnancy outcome

Early case reports and small series described adverse, sometimes fatal, maternal outcomes in pregnant patients with scleroderma. Large retrospective case–control studies, and the only prospective study by Steen (2007*), showed that pregnancy does not profoundly alter the disease. In a study of 133 pregnancies in 69 patients, no change in disease-related symptoms was found in 88%, improvement occurred in 5%, and aggravation in 7% of pregnancies. Cutaneous disease did not change much and progression of skin disease was uncommon during pregnancy or post-partum in any of the studies. Usually, Raynaud's phenomenon improved and arthralgias and reflux worsened during pregnancy, whereas cardiopulmonary problems essentially remained unchanged in women with SSc.

Serious organ manifestations of SSc can threaten the outcome of pregnancy (Steen, 2007*). The renal manifestations of SSc, including hypertension, progressive renal failure or proteinuria, can appear at any stage

of pregnancy and usually present as hypertension. A fourfold increase of hypertensive disorders including pre-eclampsia was found in a retrospective study of 504 pregnancies in women with SSc. Risk factors for renal crisis are early diffuse SSc and rapidly progressing skin disease. Treatment with high-dose prednisolone may be an additional risk factor (Steen, 2007*). Case–control studies have shown that renal crisis does not occur more often in pregnant than in non-pregnant patients with SSc, and has a frequency varying between 2% and 11%. Successful pregnancy after the occurrence of a renal crisis has been described in patients continuing angiotensin-converting enzyme (ACE) inhibitors throughout pregnancy in spite of the foetal risk associated with these drugs.

Another serious complication is pulmonary hypertension, with a survival rate of about 2.8 years and a 30–50% risk of maternal mortality in cases of pregnancy. Fortunately, a multidisciplinary team approach has now improved pregnancy outcome in these high-risk pregnancies.

Retrospective and prospective studies have shown an increased frequency of prematurity in SSc. A retrospective study of 109 SSc pregnancies found preterm deliveries (25% vs 12%) and severe preterm deliveries (<34 weeks) (10% vs 5%), IUGR (6% vs 1%) and very-low-birth-weight babies (5% vs 1%) significantly more common in women with SSc than in healthy women. This may be attributable to disorders of placental perfusion secondary to the fibrosing process and to the vasculopathy associated with scleroderma. In a large retrospective study no general increase in miscarriages was found in patients with SSc, except for women with longstanding diffuse scleroderma.

10.2 Special problems

In case, Raynaud's syndrome remains severe during pregnancy vasodilators such as nifedipine can be used. Gastro-oesophageal reflux often becomes aggravated in late pregnancy. It can be managed with anti-reflux measures such as frequent small food intake, avoidance of a prone position after dinner and H2 blockers. All proton pump inhibitors, except for rabeprazole, can also be used if necessary. Although ACE inhibitors are contraindicated during late pregnancy, should renal crisis occur, their use may be life saving for the mother.

10.3 Conclusion

Patients with SSc can have successful pregnancies. The risk of an adverse pregnancy outcome is greater in patients with the diffuse form than with the limited form of SSc. Women with early diffuse and rapidly progressing disease should wait until their SSc is less active. Patients with severe organ involvement, such as cardiomyopathy, severe restrictive lung disease, pulmonary hypertension, malabsorption or severe renal insufficiency, should probably be discouraged from becoming pregnant.

11. Polymyositis and dermatomyositis

Only 14% of female patients present with idiopathic inflammatory myopathies (IIM) during childbearing years. Therefore, the pregnancy experience for women with polymyositis (PM) or dermatomyositis (DM) is limited.

11.1 PM and DM during pregnancy and pregnancy outcome

To date, 62 pregnancies in 52 patients with PM/DM have been described in case reports or small retrospective series: 49% of the patients had disease onset before pregnancy, 36% manifested IIM during pregnancy and in 15% of the patients the disease started post-partum. Pregnancy outcome in mothers with IIM varied with disease severity (Silva *et al*, 2003*; Doria *et al*, 2004*). In patients with active disease during pregnancy, 43% ended with foetal or neonatal death and 33% of infants showed IUGR. By contrast, patients with inactive IIM during pregnancy delivered healthy babies of normal birth weight in more than 85% of the cases. In patients who were diagnosed with IIM during pregnancy, the percentage of foetal survival was 48%. Sixty-three per cent of cases diagnosed in the first trimester resulted in pregnancy loss or neonatal death or foetal growth restriction, whereas most patients diagnosed in the second and third trimester had live infants (77%), despite a high frequency of premature births (23%) (Silva *et al*, 2003*). Raised levels of creatine kinase have occasionally been detected in neonates of mothers with PM or DM. No sign of IIM developed in any of the children.

The course of inflammatory myopathies does not appear to be influenced by pregnancy, even though muscle impairment may be increased by weight gain during pregnancy (Silva *et al*, 2003*).

11.2 Special problems

When PM/DM is active during pregnancy, high-dose prednisone 1 mg/kg/day should be started and maintained until the serum creatine kinase levels have returned to normal. If the response to prednisone is insufficient, cyclosporine A or azathioprine can be added. In anecdotal cases, IIM refractory to high-dose glucocorticoid treatment has responded to treatment with intravenous immunoglobulin during pregnancy.

11.3 Conclusion

The data from case reports and small series indicate that most women with PM/DM with inactive disease at conception have normal pregnancies with a good outcome. Relapses at a quiescent stage seem rather uncommon during pregnancy. In contrast, women with active disease at conception or disease onset during pregnancy are at high risk of an adverse pregnancy outcome.

12. Familial Mediterranean fever

12.1 FMF during pregnancy and pregnancy outcome

The course of FMF during pregnancy is variable. Both complete remission and unchanged or aggravated disease with frequent attacks have been reported. Early studies found an increased rate of miscarriage of up to 25% in women with untreated FMF (Ben-Chetrit *et al*, 2010). An increase in recurrent abortion was also found in a population-based study that compared the outcome of 239 pregnancies in patients with FMF with the outcome of pregnancies in healthy subjects. An increased rate of preterm birth was found in patients with FMF. Perinatal outcome did not differ between children born to patients with FMF or to healthy mothers.

12.2 Special problems

Continuous treatment with 1–2 mg/day of colchicine suppresses acute attacks of FMF and reduces the occurrence of amyloidosis. Patients refusing colchicine treatment or treated with inadequate doses may enter pregnancy with renal amyloidosis. A deterioration of renal function during or shortly after pregnancy may occur in these patients with high serum creatinine and proteinuria >2 g/24 h.

Treatment with colchicine during pregnancy has raised concern owing to its transplacental passage and its ability to inhibit mitosis. However, several retrospective studies, comprising a total of 881 pregnancies, showed no increase in congenital malformations or chromosomal aberrations in offspring exposed at conception or during pregnancy. In one study, amniocentesis was performed to detect chromosomal aberrations in colchicine-exposed pregnancies; no increase was found compared with the number expected for maternal age distribution (Ben-Chetrit *et al*, 2010).

12.3 Conclusion

Attacks of serositis and fever may lead to early uterine contractions, resulting in miscarriage or preterm delivery (Ben-Chetrit *et al*, 2010). In addition, untreated FMF increases the risk of developing amyloidosis. Therefore, continuation of colchicine before a planned pregnancy and throughout pregnancy is recommended.

13. Vasculitides and pregnancy

The most common primary types of vasculitides are Takayasu arteritis (TA), polyarteritis nodosa, granulomatosis with polyangiitis (GPA, formerly called Wegener's granulomatosis), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg–Strauss syndrome). There is limited information on pregnancy outcome in these diseases because most of the primary vasculitides occur in older people and are more common in men.

Of the large- and medium-vessel vasculitides, only TA is presented (table 2). The risk of TA associated with pregnancy is mainly due to arterial hypertension and/or pre-eclampsia with a greater risk in more severe and extensive cases of the large-vessel arteritis.

Table 2 Interaction of pregnancy and vasculitis

Disease	No. of pregnancies reported	Effect of pregnancy on disease	Risk of maternal complications in pregnancy	Risk of pregnancy complications	Risk of foetus/neonate
<i>Takayasu arteritis</i>	160	Unchanged in 72% Improvement in 20%	Dependent on type of involvement. Progression of renal insufficiency, congestive heart failure	Hypertension in 30–44% Pre-eclampsia in 12–16%	Mostly favourable outcome, intrauterine growth restriction, low birth weight if severe maternal disease
<i>Granulomatosis with Polyangiitis</i>	62	Relapse in 40% during pregnancy, also when in remission at conception	Onset during pregnancy; risk of severe maternal disease	Pre-eclampsia in 22%, prematurity in 40%	Abortion, intrauterine growth restriction, low birth weight
<i>Eosinophilic Granulomatosis with Polyangiitis</i>	23	No major effect on disease activity	Asthma, aggravation of cardiac disease, skin rash	No increased risk	Rare, mostly favourable outcome
Microscopic polyangiitis	20	No major effect on disease activity	Renal disease, pulmonary haemorrhage	Prematurity	Transfer of MPO-ANCA to foetus and pulmonary–renal syndrome in neonate rarely occurs

ANCA, antineutrophil cytoplasmic antibody; MPO, myeloperoxidase.

GPA, EGPA and microscopic polyangiitis (MPA) are small-vessel, necrotising vasculitides associated with the presence of antineutrophil cytoplasmic antibodies (ANCA). The most common manifestations of these diseases are in the respiratory tract and the kidneys. Reports on pregnancy in GPA, EGPA, and MPA are extremely rare owing to the infrequent occurrence of these diseases in women of childbearing age (Sangle *et al*, 2015). The literature consists nearly exclusively of case reports published over a period of decades with variance in patient characteristics and management. Old reports tend to describe more adverse pregnancy outcomes than recent ones, owing to less developed obstetric medicine and fewer treatment modalities at that time. A

retrospective study of 22 pregnancies in women with ANCA-positive vasculitis (13 GPA and 1 MPA) in remission and with main disease manifestations in ear, nose, throat and kidney found rather good pregnancy outcomes. Only two children were premature, and a relapse occurred in one pregnancy only (Tuin *et al*, 2011).

A recent retrospective study of 51 pregnancies reported a lower median gestational age but a similar median birth weight in these pregnancies (Sangle *et al*, 2015). Outcomes are poorer if pregnancies occur during active vasculitis with higher risk of pregnancy loss or induced abortion, prematurity or even the mother's death. Pregnancy does not seem to have a major impact on vasculitis activity. Life-threatening manifestations can occur, especially in patients with vasculitis-related cardiac or renal damage (Pagnoux *et al*, 2011*).

13.1 Treatment of active vasculitis during pregnancy

Active vasculitis in patients with TA, GPA, EGPA and MPA during pregnancy requires prompt and aggressive immunosuppressive therapy. Prednisone is the main option, with doses adjusted to the type and severity of organ manifestations. Systemic manifestations may require treatment with high-dose oral prednisone (0.5–1.5 mg/kg/day), or intravenous pulse methylprednisolone (0.5–1 g daily for three consecutive days). As soon as the disease is controlled, prednisone can be tapered to the lowest effective dose. In refractory cases azathioprine can be added. At life-threatening aggravation during the second and third trimester cyclophosphamide or Rituximab may be required. If GPA is limited to the upper airways, local treatment, antibiotics and, if necessary, low-dose oral prednisone may be sufficient. In patients with EGPA, special care should be taken in monitoring bronchospasm during pregnancy and post-partum. Some patients refractory to glucocorticoids respond to the addition of intravenous immunoglobulin therapy.

13.2 Conclusion

Conception in a stage of quiescent or well-controlled disease is essential for good maternal and foetal outcome in all forms of vasculitis. Conception during active disease should be discouraged. Maternal and foetal outcome has been satisfactory in most patients with TA, GPA and EGPA when the disease activity was well controlled. However, disease onset may occur during pregnancy as well as post-partum. Patients with active disease at conception or disease onset during pregnancy are at increased risk of adverse pregnancy outcomes since options for effective treatment are limited. The severity of the initial manifestations of vasculitis does not predict the activity of the disease during pregnancy. A disease flare during pregnancy or post-partum is possible even when the vasculitis was quiescent at conception. Frequent controls during pregnancy and post-partum are therefore mandatory.

14. Behçet disease

Behçet disease (BD) affects both genders at 15–45 years of age, therefore pregnancy in patients with BD is not rare. The interaction of pregnancy and BD has been recorded in case reports and several retrospective series. No prospective study has been conducted.

14.1 BD during pregnancy and pregnancy outcome

Four retrospective series, comprising 222 pregnancies in women with BD, showed improvement or even remission in 53–80%. A relapse was reported in 16–35.5%, respectively, consisting of oral or genital ulcers, arthritis and eye inflammation. The proportion of BD flares tended to be lower in patients treated with colchicine (Noel *et al*, 2013). Serious maternal complications were rare, with one Budd–Chiari syndrome occurring post-partum, one deep vein thrombosis and one pulmonary embolism. Decidual vasculitis and intervillous inflammation have been described in full-term and first trimester placentas of patients with BD.

A case–control study comparing 77 pregnancies in patients with BD and 288 pregnancies in healthy controls showed a significantly higher rate of adverse outcome in patients with BD than in the control group (26% vs 2%). Miscarriage occurred in 21% of patients with BD compared with 5.2% in healthy women. Surgical delivery was more common in women with BD (15% vs 5%). Hypertension and gestational diabetes mellitus occurred more often in pregnant patients with BD. No difference was found in neonatal health or birth weight. An association between history of deep vein thrombosis and the risk of obstetric complications has been described in one of these reports (Noel *et al*, 2013).

Transient neonatal BD has been recorded in six case reports. Clinical symptoms were oral and genital ulcers, skin lesions, bloody diarrhoea, stridor and neurological involvement developing within 1 week after birth and resolving by 6–16 weeks after birth. Symptoms subsided in five cases spontaneously or after receiving treatment with prednisone. One infant died of generalised seizures. The pathogenesis of neonatal BD is unclear, but transplacental passage of maternal immunoglobulins is suspected.

14.2 Special problems

BD is associated with an increased risk for thrombosis. In spite of this, no recommendation for routine use of low-dose aspirin or anticoagulation with heparin during pregnancy has been identified in the literature or among experts. Patients with BD with previous thromboembolic events should receive heparin during pregnancy. For mucocutaneous, ocular and articular manifestations of BD, glucocorticoids, colchicine, azathioprine and cyclosporine have been shown to be effective. Severe uveitis may respond to infliximab.

14.3 Conclusion

Available data suggest that pregnancy does not aggravate maternal disease, though a relapse may occur in about 20% of BD pregnancies. The flares concern predominantly the skin, the mucosa and the articulations, and occur mainly during the first trimester. There does not seem to be any increase in obstetric complications, but the available data are sparse and prospective data are needed (Noel *et al*, 2013). Serious maternal complications or neonatal BD are rare, but because they are unpredictable careful monitoring during pregnancy and post-partum is required.

15. Drug treatment during pregnancy and lactation

Recommendations from a EULAR task force on antirheumatic drugs and pregnancy have been published in 2016 (Götestam Skorpen *et al*, 2016*) (Table 3). An adjustment of treatment is necessary for patients wishing to become pregnant or for those already pregnant. Treatment must be tailored to the individual patient according to disease activity and secure effective maternal disease control, as well as safety of the foetus. Drugs excluded for pregnant patients are combination treatments that include methotrexate, which is foetotoxic, or new drugs not studied or which have not been used in pregnant patients. Tables 4–7 summarise information on the safety of antirheumatic drugs during pregnancy and lactation. An algorithm for a treatment strategy of patients with rheumatic disease at different stages of pregnancy is presented in figure 4. A detailed and comprehensive overview of antirheumatic drugs during pregnancy and lactation is given in several surveys.

Table 3 Points to consider for the use of antirheumatic drugs before and during pregnancy (Götestam Skorpen et al, 2016*)

Points to consider for use of antirheumatic drugs during pregnancy		Grade of recommendation
1	Conventional synthetic disease modifying anti-rheumatic drugs (csDMARDs) proven compatible with pregnancy are hydroxychloroquine, chloroquine, sulfasalazine, azathioprine, cyclosporine, tacrolimus and colchicine. They should be continued in pregnancy for maintenance of remission or treatment of a disease flare.	B
2	csDMARDs methotrexate (MTX), MMF and cyclophosphamide are teratogenic and should be withdrawn before pregnancy.	B
3	Non-selective cyclooxygenase (COX) inhibitors (non-steroidal anti-inflammatory drugs, [NSAIDs]) and prednisone should be considered for use in pregnancy if needed to control active disease symptoms. NSAIDs should be restricted to the first and second trimesters.	B
4	In severe, refractory maternal disease during pregnancy methylprednisolone pulses, intravenous immunoglobulin or even second or third trimester use of cyclophosphamide should be considered.	D
5	csDMARDs, targeted synthetic DMARDs (tsDMARDs) and anti-inflammatory drugs with insufficient documentation concerning use in pregnancy should be avoided until further evidence is available. This applies to leflunomide, mepacrine, tofacitinib and selective COX II inhibitors.	B–D
6	Among biological DMARDs (bDMARDs), continuation of anti-TNFs during the first part of pregnancy should be considered. Etanercept and Certolizumab may be considered for use throughout pregnancy due to low rate of transplacental passage.	B
7	bDMARDs rituximab, anakinra, tocilizumab, abatacept, belimumab and ustekinumab have limited documentation on safe use in pregnancy and should be replaced before conception by other medication. They should be used during pregnancy only when no other pregnancy-compatible drug can effectively control maternal disease.	D

Table 4 Antirheumatic drugs and biological agents not to be continued during pregnancy (Reproduced with permission from Østensen and Forger, Curr Opin Pharmacol 2013;13:470–5*)

Drug	Developmental toxicity reported		Recommendation
	In animals	In humans	
Methotrexate	In animals and humans		Discontinue 3 months before pregnancy*
Mycophenolate mofetil	In animals and humans		Discontinue 6 weeks before trying conception
Cyclophosphamide	In animals and humans		Withdraw before pregnancy
Leflunomide	In animals	No increase in adverse outcomes in 109 pregnancies	Stop and washout† before pregnancy
Abatacept	Toxicity in animals	Case series: no increase in adverse outcomes	Discontinue 3 months before pregnancy

Tocilizumab	Not in pharmacological doses	Register data, case series: no increase in adverse outcomes	Discontinue 3 months before pregnancy
Belimumab	Limited data		Discontinue 5 half-life before pregnancy [‡]
Anakinra			
Ustekinumab			
Tofacitinib			
Rituximab	B cell depletion in the foetus of animals and humans when given in 2nd or 3rd trimester		Discontinue 6–12 months before pregnancy
Infliximab, Adalimumab, Golimumab	No toxicity in animals	Sporadic cases, cause–effect relationship not conclusive	Discontinue at missed period or after a positive pregnancy test. For active disease refractory to other treatment, TNF inhibitors may be given during pregnancy. Monoclonal antibodies must be stopped between gestational weeks 20 and 30.
Etanercept	No toxicity in animals	Little transplacental passage	Etanercept and certolizumab can be given throughout pregnancy.
Certolizumab	No toxicity in animals	No increase in adverse outcomes in 139 pregnancies. Little transplacental passage	
Bisphosphonates	Toxicity in animals	Insufficient data on human pregnancy	Discontinue at conception

**In France, conception is allowed the day after stopping methotrexate because of its short half-life (3–4 h). Of course, folic acid is essential in these women.*

†Because of the very long half-life (18 months) of leflunomide, a washout should be done with cholestyramine 8 g three times a day or powdered activated carbon 50 g four times a day during 11 days for both. Leflunomide concentration must be monitored to allow pregnancy.

‡They should be used during pregnancy only when no other pregnancy-compatible drug can effectively control maternal disease.

TNF, tumour necrosis factor.

Table 5 Treatment of a flare with drugs compatible with pregnancy

Type of flare	Drugs compatible with pregnancy	Precaution
Acute arthritis in one or several joints; pain, stiffness	Intra-articular glucocorticoids, NSAID: diclofenac, ibuprofen, ketoprofen, mefenamic acid, naproxen, piroxicam Colchicine	NSAID must be discontinued at week 24 or 32 of gestation depending on country's recommendations
Pain	Paracetamol	1–4 g/day can be given throughout pregnancy
Systemic flare	Oral glucocorticoids	Keep at ≤ 10 mg/day in first trimester
	Methylprednisolone pulses	Shorter possible period
	Chloroquine HCQ	HCQ preferable because of less tissue distribution
	Azathioprine	Keep at 2 mg/kg/day
	Cyclosporine	Control maternal blood pressure
	Sulfasalazine	Requires folate substitution
	Tacrolimus	Be aware of higher risk of cytomegalovirus infection
	IVIg	Same cautions than in non-pregnant patient

HCQ, hydroxychloroquine; NSAID, non-steroidal anti-inflammatory drug. IVIg: intravenous immunoglobulins.

Table 6 Non-steroidal anti-inflammatory and immunosuppressive drugs during lactation

Drug	Excreted into breast milk	Adverse effect on nursing child	Recommendations
NSAID	Yes	None reported	Nursing possible: prioritize agents with short half life
Celecoxib	Yes but very low	None reported	Nursing possible
Prednisone	Yes	None reported	Nursing possible. Consider a 4h delay before breastfeeding after prednisolone if dose > 50mg/day
Chloroquine, hydroxychloroquine	Yes	None reported	Nursing possible
Colchicine	Yes	Diarrhoea: reconsider breastfeeding	Be aware of macrolide prescription in breastfed infants
IVIg	Heterogenous results	Rare	Nursing possible
Sulfasalazine	Yes	Rare	Nursing possible. Caution in premature children, G6PD deficiency and hyperbilirubinaemia
Leflunomide	Not studied	No data	Avoid

Azathioprine	Yes	None reported	Nursing possible. Caution in thiopurine methyltransferase deficient individuals
Cyclosporine	Yes	None reported	Nursing possible
Tacrolimus	Yes	None reported	Nursing possible
Methotrexate	No	No data	Avoid
Cyclophosphamide	Yes	Bone marrow suppression	Avoid
Mycophenolate mofetil	Not studied	No data	Avoid

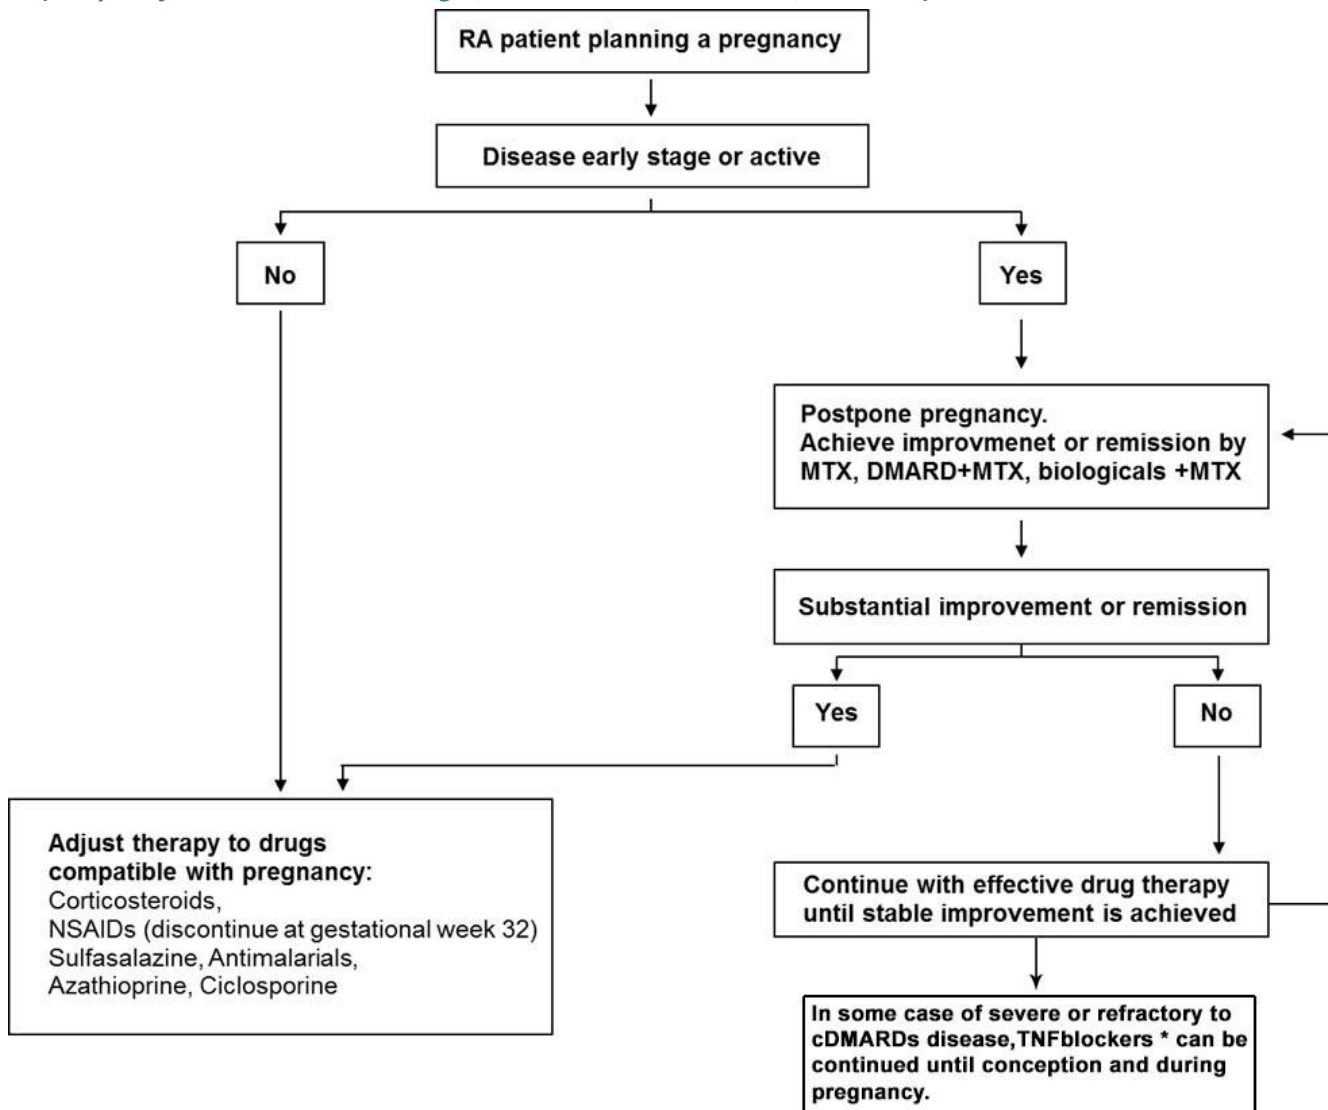

NSAID, non-steroidal anti-inflammatory drug. IVIg: intravenous immunoglobulins.

Table 7 Biological agents during lactation

Drug	Detected in milk	Adverse effect on infant	Recommendation
Etanercept	Yes, minute amount	None reported	Compatible with lactation
Infliximab	Yes, minute amount	None reported	Compatible with lactation
Adalimumab	Yes, minute amount	None reported	Compatible with lactation
Golimumab	Not studied	No data	No data*
Certolizumab	No	None reported	Compatible with lactation
Abatacept	Not studied	No data	No data*
Tocilizumab	Not studied	No data	No data*
Rituximab	Not studied	No data	No data*
Ustekinumab	Not studied	No data	No data*
Anakinra	Not studied	No data	No data*
Belimumab	Not studied	No data	No data*

**Large protein molecule, absorption unlikely due to low bioavailability. Biological DMARDS with no data on breast feeding should be avoided during lactation if other therapy is available to control the disease. Based on pharmacological properties of biological nDMARDS, lactation should not be discouraged when using these agents, if no other options are available (Götestam Skorpen et al, 2016*).*

Figure 4. Algorithm of a treatment strategy for patients with RA planning a pregnancy. In patients with stable disease, or with mild-to-moderate disease activity, treatment should be adjusted from drugs incompatible with pregnancy (eg, methotrexate) to compatible drugs. In patients with early RA or with active and uncontrolled disease activity, pregnancy should preferentially be postponed until substantial improvement in disease activity or remission is achieved. Once RA is stable, and after a switch to drugs compatible with pregnancy, conception can be attempted. DMARDs, disease-modifying antirheumatic drugs; MTX, methotrexate; NSAIDs, non-steroidal anti-inflammatory drugs; RA, rheumatoid arthritis. (Adapted from Østensen and Förger, Nat Rev Rheumatol 2009;5:382–90.)

**Most of the safety data available of TNF blockers is based on women discontinuing TNF α therapy in the first trimester. TNF blockers can cross the placenta from the end of the second trimester of gestation and little data exists on exposure throughout the pregnancy. Their use during pregnancy should be based on a collegial decision after discussion with the patient.*

- Drugs to be withdrawn before a planned pregnancy: methotrexate, cyclophosphamide, leflunomide, mycophenolate mofetil, abatacept, tocilizumab, belimumab, ustekinumab and rituximab.
- Drugs that can be continued until conception: TNF inhibitors. TNF inhibitors differ in structure and show differences in transplacental passage. Complete monoclonal antibodies infliximab, adalimumab and golimumab are actively transported through the placenta, whereas certolizumab pegol and

etanercept has minimal passage to the foetus and may be a choice when active disease in pregnancy requires a TNF inhibitor.

- Drugs that are compatible with pregnancy: colchicine, sulfasalazine, azathioprine, cyclosporine and tacrolimus.
- Drugs that can be safely administered throughout pregnancy: antimalarial agents, glucocorticoids and analgesics such as paracetamol (acetaminophen).
- Drugs that can be safely administered until gestational week 24 in some countries as in France or gestational week 32 in others: NSAIDs.

Supplementation with folic acid, calcium and vitamin D (the latter especially in women taking glucocorticoids or low molecular weight heparin) should be recommended.

When immunosuppressive or biologic agents have been used during pregnancy, children must be considered as immunocompromised until 6 months of life (live attenuated vaccines are contraindicated during this period). Paediatricians must be informed of the use of such treatment during pregnancy.

16. Vaccinations

Vaccinations need to be updated before pregnancy.

Reminder: live attenuated vaccines are contraindicated during pregnancy and/or when patients receive immunosuppressive agents, biotherapy or corticosteroid up to 10 mg per day for more than 2 weeks.

Pertussis is a highly infectious disease that can cause serious complications. Newborn babies are especially vulnerable until they have had at least 2 doses of the vaccine (i.e. until they are 3-4 months old). Babies under 3 months old are at greatest risk of complications and death from pertussis. So it is important for women to get the whooping cough vaccine before or during pregnancy (according to each country recommendations).

Pregnant women have to be vaccinated against influenza viruses because flu is more likely to cause severe illness in pregnant women than in healthy women who are not pregnant and because vaccination seems to increase the likelihood of having a live birth. Many scientific studies support the safety of flu vaccine in pregnant women and their babies.

17. Risk assessment and monitoring of pregnancies

Risk assessment of possible maternal or foetal risks during a future pregnancy is essential. Major risks are active disease at conception, a flare during pregnancy, conception in a stage of active organ involvement or at severe organ damage, presence of antiphospholipid and antibodies against SSA (Ro) and SSB (La). A clinical investigation and laboratory tests will show the presence of risk factors for a future pregnancy, and will allow

stratification into a high-, moderate- or low-risk profile. Treatment adjustment and type and frequency of monitoring will depend on the risk profile of the individual patient.

At the start of pregnancy a complete clinical and laboratory assessment is necessary in order to monitor disease activity. High-risk pregnancies are best monitored by an interdisciplinary specialist team, including the internist or rheumatologist, obstetrician and paediatrician. The frequency of visits depends on disease severity, type of treatment and the stage of pregnancy. In uncomplicated cases, visits once a month can be scheduled until gestational week 20, then more often in late pregnancy. The diagnosis of a disease flare must be based on clinical and laboratory assessment. Regular assessment of foetal growth can predict whether the foetus is at risk. Doppler flow techniques allow evaluation of the uteroplacental and umbilical circulation. Electronic foetal heart rate monitoring has proved effective for detecting foetal distress. Foetal echocardiography is important for detecting myocarditis in a foetus with congenital heart block. The best guarantee for an optimal pregnancy outcome is close monitoring of mother and foetus and appropriate treatment of complications during pregnancy.

Figure 5

Normal uterine artery Doppler waveforms

Abnormal uterine artery Doppler

18. Counselling women

Better treatment and better prognosis of many of the rheumatic diseases have resulted in more patients considering pregnancy. A previous study found that 95% of women with rheumatic diseases wanted children, even those with disabling disease. Pregnancy in patients with connective tissue disease requires preconceptional counselling (see online in-depth discussion). The task of the physician is to discuss the possible problems, identify risks and organise adequate monitoring during pregnancy and post-partum.

In Western affluent countries the birth rate has decreased to between one and three children. At the same time women have postponed the time for having a first child to the fourth decade of life. This means that

many patients will plan their first pregnancy at about the age of 35 years. The internist or rheumatologist counselling a patient with rheumatic disease should consider the stage of the disease, disease activity and presence of factors that increase the risk for an adverse pregnancy outcome, especially antiphospholipid antibodies, anti-SSA antibodies or organ damage. An early stage of disease implies that the pattern of disease severity is not yet apparent and complications might still develop in the near future. SSc is an example. A patient with active rheumatic disease should postpone pregnancy until remission or stable disease is achieved and has persisted for at least 6 months. Before pregnancy, access to familial and social support should be evaluated. Therefore, it is advantageous to include the patient's partner or a family member in preconceptual counselling. In order to prepare for the task of child caring after delivery, consulting an occupational therapist is advisable for the patient with impaired function. A meeting with an interdisciplinary team including a physiotherapist, an occupational therapist and a social worker can help to prepare the rheumatic mother for parenting. Finally, the possible difficulties of parenting should be discussed.

Drug treatment before and during pregnancy needs to be discussed. It is important that the treating physician warns against discontinuation of all treatment when an attempt at conception is made. Withdrawal of drug treatment may result in a disease flare. The better approach is to adjust treatment and continue with drugs that are compatible with first trimester exposure. Other physicians, especially the gynaecologist, involved in patient treatment should be informed about necessary antirheumatic therapy in order to avoid contradictory advice.

SUMMARY POINTS

- The interaction of rheumatic diseases and pregnancy is variable and related to the pathogenesis of the maternal rheumatic disease.
- Rheumatoid arthritis improves in 40–75% of patients during pregnancy; the chance of improvement is highest in patients negative for rheumatoid factor and citrullinated antibodies.
- Ankylosing spondylitis remains active during pregnancy in about 80% of patients, with frequent aggravation of symptoms during the second trimester.
- Polyarticular or oligoarticular juvenile idiopathic arthritis is not reactivated by pregnancy but tends to improve during gestation.
- Symptoms of primary Sjögren's syndrome are not influenced by pregnancy.
- Systemic lupus erythematosus (SLE) may be associated with a bad obstetrical outcome, in particular in active disease.
- Pregnancy can induce a flare of SLE.
- The presence of SSA/SSB antibodies is associated with a risk of neonatal lupus syndrome.
- Successful pregnancy is possible in women with systemic sclerosis provided that they have no severe organ manifestations.
- Most women with polymyositis or dermatomyositis with inactive disease at conception have normal pregnancies with a good outcome.
- The course of familial Mediterranean fever during pregnancy is variable, with the best chances for a good outcome achieved by continuing colchicine during pregnancy.
- Women with any type of vasculitis should attempt pregnancy only at a stage of quiescent and well-controlled disease.
- Pregnancies in women with active rheumatic disease or vasculitis, in women with severe organ manifestations or with repeated high-titre phospholipid antibodies or SSA/SSB antibodies are high risk.
- Blood pressure increase has a strong association with unfavourable pregnancy outcomes. New onset of hypertension in pregnancy may be a first sign of emerging pre-eclampsia or other organ involvement

Drug treatment requires adjustment to the stage of pregnancy and must be tailored according to maternal disease severity and safety for the foetus. High-risk pregnancies require a multidisciplinary approach with frequent monitoring of mother and child during pregnancy and post partum.

Part II: antiphospholipid syndrome

LEARNING OBJECTIVES

- ➔ Recognise the classical manifestations of antiphospholipid syndrome (APS) (thrombotic events and pregnancy morbidity) and the laboratory assays for detection of antiphospholipid antibodies
- ➔ Recognise that APS may present as a primary form as well in association with other systemic autoimmune diseases, mainly systemic lupus erythematosus
- ➔ APS is a 'systemic' disease: neurological, cardiac, renal, and cutaneous manifestations may be present
- ➔ Design a diagnostic screening algorithm for the individual patient
- ➔ Critically evaluate the limited scientific evidence for the diagnosis and treatment of patients with antiphospholipid antibodies with and without APS
- ➔ Develop treatment strategies for patients with APS, tailored to the clinical picture

1. Introduction

The antiphospholipid syndrome (APS) is a systemic autoimmune disorder characterised by arterial and/or venous thrombosis and/or pregnancy morbidity, associated with the presence of a specific group of autoantibodies called antiphospholipid antibodies (aPL) (Miyakis et al, 2006*). APS was initially described in patients with systemic lupus erythematosus (SLE), but it was soon recognised as a primary form in those people who did not have features (clinical and serological) of other systemic autoimmune diseases. A European study of 1000 patients showed that APS was associated with SLE in 36% of the cases.

Although APS is largely recognised as a disease of young women, owing to the association with SLE and pregnancy loss, men can also be affected. It is estimated that aPL can be found in 9.5% of the patients with unexplained venous thrombosis and in 13.5% of those with stroke (Andreoli et al, 2013).

However, the presence of aPL is not limited to those people who have the typical picture of APS. These autoantibodies are detectable in several different conditions, mainly in patients with systemic autoimmune diseases, but also in infectious conditions, cancer, use of particular drugs and even in healthy individuals (table 1).

Table 1 Conditions in which antiphospholipid antibodies have been reported

Systemic autoimmune disorders	Infection
– Systemic lupus erythematosus	– Leprosy
– Rheumatoid arthritis	– Syphilis

The relevance of testing for aPL concerns their pathogenic role. In vitro and in vivo studies in animal models showed that aPL are mediators of both thrombosis and pregnancy morbidity by the engagement of multiple pathogenic mechanisms involving inflammation and disruption of the coagulation pathways. Moreover, aPL are considered as a risk factor for the development of APS, so they should be assessed in patients with systemic autoimmune diseases in order to establish an adequate prophylaxis.

Treatment of APS means prophylaxis. It is primary in those individuals who are aPL carriers and should be prevented from the development of their first event; and secondary in those patients who need to be protected from recurrence of either thrombosis or pregnancy morbidity.

2. Antiphospholipid antibodies

aPL are a family of the immunoglobulins IgG, IgM, IgA or a combination of these isotypes, which were initially thought to recognise anionic phospholipids, particularly cardiolipin (Giannakopoulos and Krilis, 2013*). Over the years, this concept has changed and different specificities have been described for aPL (table 2). The main finding was that aPL mostly recognise phospholipid-binding proteins rather than the phospholipids.

Table 2 Different specificities of antiphospholipid antibodies

Antibodies to phospholipids
Cardiolipin
Phosphatidylserine
Phosphatidic acid
Phosphatidylinositol
Phosphatidylcholine
Phosphatidylethanolamine
Antibodies to phospholipid-binding proteins
β 2-Glycoprotein I (β 2GPI) Factor XIIIG
Prothrombin C4b binding protein
Annexin V Complement C4 and C5
Protein C Heparin sulphate
Protein S Thrombin
Low and high molecular weight kininogens Other

2.1 Lupus anticoagulant

Lupus anticoagulant (LA) is a functional measurement of the ability of heterogeneous aPL that interfere with phospholipid-dependent stages of blood coagulation in vitro and inhibit both the intrinsic and common pathways of coagulation. Paradoxically, LA-positive results are associated with a thrombotic tendency rather than bleeding, which is generally associated with coagulation inhibitors. LA has been reported in a wide variety of patient populations, ranging from those with autoimmune diseases (eg, SLE, rheumatoid arthritis (RA)), drug exposure (eg, chlorpromazine, procainamide and hydralazine), infections and lymphoproliferative disorders to individuals with no apparent underlying disease. The estimated prevalence in patients with SLE ranges from 6% to 65%. Not all patients with LA have anticardiolipin (aCL) and vice versa. In most cases LA are specific for either phospholipid-bound β 2-glycoprotein I (β 2GPI) or prothrombin. LA are strongly associated with the risk of thrombosis and adverse obstetrical outcome (Lockshin *et al*, 2012*).

2.2 Anticardiolipin

The aCL test was originally described in 1983 as a radioimmunoassay. The first aCL enzyme-linked immunosorbent assay (ELISA) was carried out in 1985, using cardiolipin as antigen and foetal calf serum or adult bovine serum in the buffers. The addition of serum was essential for performance of the assay, owing to the presence of β 2GPI, a glycoprotein that binds negatively charged phospholipids, such as cardiolipin itself. Therefore, an aCL assay can detect several subpopulations of autoantibodies—that is, those directed against phospholipid-binding proteins such as β 2GPI (β 2GPI-dependent aCL), the phospholipid itself or against the phospholipid-binding protein/phospholipid complex. As a consequence, a positive test for aCL may be less specific for APS, since it is commonly found in non-autoimmune conditions, especially infections. These aCL are

usually IgM and low titre and are not associated with aPL-related clinical features. Instead, the risk of thrombosis, recurrent pregnancy loss and thrombocytopenia has been associated with high levels of aCL. IgG isotypes are more related to clinical complications than are IgM isotypes. The role of IgA aCL is still controversial.

2.3 Antibodies to β 2-glycoprotein I

In 1990, two independent groups identified β 2GPI as the plasma cofactor required for aCL binding to cardiolipin. β 2GPI is a normal plasma glycoprotein, a single-chain 50 kD polypeptide consisting of 326 amino acids arranged into five short consensus repeats or domains. Its function is not completely understood, although it may act as a natural anticoagulant. ELISA tests using β 2GPI coated in the absence of phospholipids were developed for the detection of antibodies against human β 2GPI. It was found that anti- β 2GPI were more specific than aCL in predicting thrombosis and differentiating pathogenic (autoimmune) from non-pathogenic (infection or drug induced) antibodies, since β 2GPI is an absolute requirement for binding of autoimmune aCL to cardiolipin in ELISA. Moreover, it is estimated that 3–10% of patients with APS have anti- β 2GPI as the only positive test.

2.4 'Non-criteria' aPL

As described in table 2, aPL may have different specificities other than cardiolipin and β 2GPI—for example, antiprothrombin, antiphosphatidylethanolamine, anti-Annexin V, antiprotein C and S, and others. These antibodies were not recognised as laboratory criteria in the last international consensus, mostly owing to weak and discordant evidence for the association with APS manifestations. To this group belong also IgA aCL and anti- β 2GPI. However, there is much interest in this field and an international task force is currently examining the subject (Bertolaccini et al, 2011).

2.5 Standardisation concerns

Although they have different methodological approaches (LA is a functional test that explores the coagulation in vitro; aCL and anti- β 2GPI are detected by quantitative ELISAs that can test different isotypes), all three tests still suffer from poor standardisation (Pengo et al, 2009). Despite many international efforts for more than 20 years, reports of inconsistencies, interassay and interlaboratory variation, and problems with the interpretation and clinical value of the tests still exist. As an example, there are still no international units for the measurement of anti- β 2GPI, so results are reported arbitrarily. Therefore, the consistency of the diagnosis of APS is greatly

affected by laboratory procedures, making it difficult to compare patients from place to place. International committees and task forces are working to deal with these problems (Pierangeli et al, 2011*).

3. Origin of aPL

The origin of aPL and mechanisms involved in their production are not understood. The origin of aPL was extensively investigated and several research groups have induced high levels of aPL in experimental animals by immunisation with β 2GPI. However, although immunisation with foreign β 2GPI can induce pathogenic aPL, it is unlikely that aPL production is induced with foreign β 2GPI in patients with APS. The observation that aPL of the autoimmune type may be associated with thrombosis in patients with Epstein–Barr virus, cytomegalovirus, hepatitis C virus, adenovirus or parvovirus suggests that certain infections may induce autoimmune aPL that are not transient.

Recent data show that aPL may be induced in experimental animals by immunisation with products from bacteria or viruses, supporting the hypothesis that these antibodies may be generated after incidental exposure or infection, a mechanism involving ‘molecular mimicry’. Immunisation of mice with viral and bacterial peptides with function and sequence similar to the phospholipid-binding site of β 2GPI (table 3) induced high levels of aPL and anti- β 2GPI. These peptide-induced aPL can also enhance thrombosis and activate endothelial cells in vivo and in vitro (Giannakopoulos and Krilis, 2013*).

Table 3 International classification criteria for definite antiphospholipid syndrome. (Modified from Miyakis et al, J Thromb Haemost 2006;4:295–306*)

Clinical criteria	
<i>Vascular thrombosis</i>	<i>Pregnancy morbidity</i>
<ul style="list-style-type: none"> One or more clinical episodes of arterial, venous, or small-vessel thrombosis, with the exception of superficial venous thrombosis, in any tissue or organ. Thrombosis must be confirmed using imaging or Doppler studies or histopathology. For histopathological confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall 	<ul style="list-style-type: none"> One or more unexplained death of a morphologically normal foetus at or beyond the 10th week of gestation One or more premature birth (<34 weeks of gestation) of a morphologically normal neonate, because of eclampsia, severe pre-eclampsia and placental insufficiency Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation (excluded maternal anatomical or hormonal abnormalities and chromosomal cause)
Laboratory criteria	
<ul style="list-style-type: none"> Lupus anticoagulant (LA), detected according to the guidelines of the International Society on Thrombosis and Haemostasis (scientific subcommittee on LAs/phospholipid-dependent antibodies), is considered positive if present in plasma, on two or more occasions at least 12 weeks apart Anticardiolipin antibodies of IgG and/or IgM isotype measured by a standardised ELISA are considered positive if present in serum or plasma, in medium or high titre (ie, >40 GPL or MPL, or >99th centile), on two or more occasions, at least 12 weeks apart 	

- Anti- β_2 -glycoprotein I antibodies of IgG and/or IgM isotype measured by a standardised ELISA, according to recommended procedures, are considered positive if present in serum or plasma, in titre >99th centile, on two or more occasions, at least 12 weeks apart

ELISA, enzyme-linked immunosorbent assay; GPL, IgG phospholipid units; MPL, IgM phospholipid units.

4. Pathogenic mechanisms of aPL

Several animal studies of both thrombosis and pregnancy loss have shown that aPL are pathogenic. aPL exert their pathogenic action through interaction with many different cell types (Giannakopoulos and Krilis, 2013*).

Recent research indicates the central role of endothelial cells, monocytes, platelets and complement in inducing thrombosis and foetal death in APS. Endothelial cells and monocytes can be activated by aPL with anti- β_2 GPI activity. In turn, endothelial cells express adhesion molecules such as intercellular adhesion molecule 1, vascular cell adhesion molecule 1 and E-selectin, and both endothelial cells and monocytes upregulate the production of tissue factor. Activated platelets increase the expression of glycoprotein IIb–IIIa and the synthesis of thromboxane A₂. Nuclear factor- κ B (NF- κ B) and p38 mitogen activated protein kinase are important mediators of these processes. Additionally, interaction of aPL with proteins implicated in clotting regulation, such as prothrombin, factor XII, protein C and plasmin, may hinder inactivation of procoagulant factors and impede fibrinolysis.

Pierangeli et al proposed that after activation of endothelial cells, monocytes and platelets by aPL, a procoagulant state is induced, mainly mediated by the increased synthesis of tissue factor and thromboxane A₂ (Pierangeli et al, 2011*). Activation of the complement cascade may ‘close the loop’ and provoke thrombosis, often in the presence of a ‘second hit’.

What is a ‘second hit’? The so called ‘two hits hypothesis’ claims that aPL alone are not sufficient to generate thrombosis, but they require ‘activation’ by a second triggering factor. Traditional cardiovascular risks factors may play an important role at this point. Such risk factors are present in more than 50% of patients with APS, with a recent epidemiological study showing that the risk of myocardial infarction or stroke in young women with LA multiplies in those who smoke or take oral oestrogenic therapy.

A different mechanism is claimed for obstetric disease. Thrombotic events do not appear to play a major role in obstetric APS, whereas direct reactivity of β_2 GPI-dependent aPL on decidual and trophoblast cells was reported. There is probably a local tropism of the autoantibodies to the placenta, since a local expression of β_2 GPI was shown in both physiological conditions and in women with APS. β_2 GPI is present on placental membranes: binding of autoantibodies directed against this protein may modulate several cell biological functions producing a state of acute inflammation and complement activation, inhibition of trophoblast growth and differentiation and, finally, defective placentation, inducing an inflammatory phenotype on decidual cells. The presence of β_2 GPI has been demonstrated in vivo on endothelial cells of uterine vessels and trophoblast in pregnant mice. This shows that proinflammatory factors are probably not needed for uterine and placental localisation of β_2 GPI

that is probably dependent on hormonal changes. The role of anti- β 2GPI as major players in the pathogenesis of placental damage is also supported by the detection of anti- β 2GPI in the eluates from human APS placentas.

In vitro studies showed that aPL antibodies, especially anti- β 2GPI, can disrupt the anticoagulant annexin 5 shield on trophoblast and endothelial cell monolayers. β 2GPI binds human trophoblast through the phospholipid-binding site in the fifth domain of the molecule. It has been shown that a synthetic peptide (TIFI) obtained from human cytomegalovirus, is similar to the β 2GPI phospholipid-binding site and therefore may compete with β 2GPI, thus displacing the molecule from the cells' surface and inhibiting the binding of aPL to the target tissue. Repeated infusions of TIFI protected naïve pregnant mice from foetal loss induced by human aPL IgG. This is indirect evidence that anti- β 2GPI play a major role in defective placentation. This supports the in vitro results that showed the ability of aPL to modulate trophoblast cellular functions at different levels (Meroni et al, 2012).

A number of animal models for aPL-induced pregnancy loss exist, therefore many different pathogenic mechanisms are likely to be involved. For instance, the role of acute inflammation and complement activation has been greatly debated. aPL were shown to activate the complement system with subsequent placental damage mediated by neutrophils. On the other hand, pregnant mice deficient in complement C3 or C5 or treated with an inhibitor of C3 convertase did not experience foetal loss upon immunisation with aPL. This observation might be an additional explanation for the protective role of heparin because of its anti-complement activity. Human placentas have also been studied to clarify the role of complement, in both deposition and activation. Although case reports failed to show any complement deposition in abortive material from patients with APS, prospective studies did find complement deposition and activation. However, this finding was not exclusive to abortive specimens, but was also found in APS placentas at term. Moreover, complement activation was not widespread and the presence of inflammatory cells was scarce; no relationship was found between complement patterns on placentas and either treatment during pregnancy or pregnancy outcome itself. As a whole, these data suggest that local activation and deposition of complement may occur at the placental level in APS human pregnancy, but do not have a major effect on the outcome.

5. Clinical manifestations

5.1 Thrombosis

The APS is a non-inflammatory autoimmune disease in which the most critical pathological process is thrombosis, which results in most of the clinical features of these patients.

Arterial or venous thrombosis, with or without a history of adverse pregnancy, can be present. Deep vein thrombosis has been the most commonly reported venous manifestation, often recurrent and accompanied by pulmonary embolism. Occlusion of the intracranial arteries is the most common arterial manifestation, with most patients presenting with stroke.

As any organ and any size of vessel may be affected, the range of clinical features is extremely wide.

5.1.1 Central nervous system

There is a very broad spectrum of central nervous system involvement in APS. Cerebral ischaemia associated with aPL is the most common arterial thrombotic manifestation. Many studies have found that aPL are associated with an increased risk for cerebral ischaemia, but some have not. The age of onset of cerebral ischaemia in APS is several decades earlier than in the typical stroke population and the ischaemic events may occur in any territory. A less common form of cerebral thrombotic disease associated with aPL is sagittal venous sinus thrombosis.

Migraine is one of the most prominent complaints in patients with APS, but its association with aPL is still controversial. Several studies have failed to show an association between the presence of aPL and migraine. Although the prevalence of headache in SLE is similar to that reported for the general population, aPL are significantly more prevalent in the group of patients with headache than in patients without.

Cognitive deficits associated with APS may vary from mild neurocognitive disorders to severe vascular dementia. Patients affected by mild cognitive dysfunction often complain of poor concentration or forgetfulness. Verbal memory deficits, decreased psychomotor speed and decreased overall productivity have been correlated with aPL. Whether these cognitive deficits result from recurrent cerebral ischaemia or whether there are other underlying mechanisms remains unknown. Psychiatric problems, such as mood disorders and psychosis, have also been associated with aPL.

Some patients with APS may exhibit features often seen in multiple sclerosis. Myelitis, balance and sensory problems not surprisingly often lead to an erroneous diagnosis of multiple sclerosis. Differential diagnosis is difficult, and compounded by a number of features—notably, single MRIs may fail to differentiate, and borderline positive aPL levels may be dismissed as being of no significance. The clinical findings of livedo point towards APS. Also, a previous history of thrombosis or pregnancy loss, an abnormal localisation of the lesions on MRI, and the response to anticoagulant therapy might be helpful in the differential diagnosis.

Seizures have been consistently associated with the presence of aPL. The cause is still unknown, but some authors have suggested direct interaction between aPL and neuronal tissue.

Less frequently described manifestations of APS include chorea, transverse myelopathy, Guillain–Barré syndrome, sensorineural hearing loss and ocular syndromes with retinal and choroidal ischaemia.

5.1.2 Heart

Several cardiac conditions apart from coronary artery disease have been reported in association with aPL. Heart valve lesions are the most common cardiac manifestations described in patients with aPL. The

prevalence of valvulopathy has been reported in 35–75% of patients with APS, according to different series. Most of the patients are asymptomatic, with around 5% of patients progressing to cardiac failure requiring valve replacement. Valve masses (vegetations) and diffuse valvular thickening are the two morphological echocardiographic patterns most frequently seen in APS. The predominant functional abnormality is regurgitation, whereas stenosis is rarely seen. Although the mitral valve is the most commonly affected site, followed by the aortic valve, isolated tricuspid valve involvement has also been described.

Acute coronary syndromes are well documented in patients with aPL. However, the association between aPL and myocardial infarction or sudden cardiac death is still debated in case–control and prospective studies. In young women myocardial infarction may present without any sign of coronary atherosclerosis.

Uncommon cardiac manifestations of APS include intracardiac thrombus, which can be misdiagnosed as a cardiac tumour, myocardial dysfunction and syndrome X, characterised by angina-like chest pain, a positive exercise test and angiographically normal coronary arteries.

5.1.3 Lungs

Patients with APS may develop a broad spectrum of pulmonary involvement. The most common pulmonary manifestation of APS is pulmonary embolism and infarction, usually seen as the first manifestation of the disease. Pulmonary hypertension is found in around 1.8–3.5% of patients with APS (a prevalence of 2.2% was found in a cohort of 1000 European patients).

Adult respiratory distress syndrome is a very rare but devastating clinical syndrome with a mortality of 52%, usually seen in patients with catastrophic APS.

5.1.4 Kidney

The kidney is a major target organ in APS where both arterial and venous vessels, as well as the intraparenchymatous arteries and microvasculature, may all be affected. As renal damage in SLE is primarily due to immune complex-mediated glomerulonephritis, patients with SLE and APS can develop kidney involvement owing to a combination of both processes. Moreover, the impairment of renal function in patients with SLE and aPL can also occur in the absence of APS-related manifestations. In this case, distinguishing between SLE nephritis (immune complex disease) and APS nephritis (thrombotic disease) can only be accomplished by kidney biopsy.

Renal artery occlusion and renal artery stenosis have been described in patients with APS and hypertension. The localised and stenotic (thrombotic) arterial lesions have a totally different appearance from those of renal artery disease seen in atheroma in older patients. Renal infarction may result from partial or total, transient or

permanent occlusion of the renal arteries. Thrombosis of the renal veins and thrombotic microangiopathy has also been described in APS.

5.1.5 Skin

The most frequent skin manifestations are livedo reticularis (figure 2) and skin ulcers (figure 3).

Figure 2. Irregular networks of livedo with fixed broken circular segments of the calf.

Figure 3. Skin ulcer due to antiphospholipid syndrome.

Livedo reticularis is characterised by a mottled purple reticular pattern with different localisation, extension, infiltration and regularity of the fishnet pattern. In APS, livedo reticularis is usually disseminated (present on the limbs, but also on the trunk and/or the buttocks), not infiltrated and has an irregular branching or broken pattern.

It is a powerful physical sign when suspecting APS. Moreover, it is a marker of poor prognosis and more severe disease in APS. Skin ulcers are often present in the extremities. However, extensive cutaneous necrosis associated with aPL has been reported.

Subungual splinter haemorrhages are seen in around 5% of patients with APS and their presence in a patient with aPL may alert the physician to the occurrence of other thrombotic events.

Digital gangrene has been described in patients with aPL. A variety of other cutaneous lesions, including purpura, tender nodules, papules and palmar–plantar erythema and anetoderma (figure 4), have been described in APS. Anetoderma is a rare elastolytic disorder. Recently, there has been a growing body of evidence linking primary anetoderma with a wide range of immunological abnormalities, the most common of which is the presence of aPL, with or without APS.

Figure 4. Numerous lesions of anetoderma of the arm: circumscribed areas of slack skin associated with a loss of substance on palpation.

5.1.6 Liver and gastrointestinal tract

Liver thrombosis, including Budd–Chiari syndrome, was a feature of the original clinical description of the syndrome. Liver function abnormalities are common in patients with APS, possibly as a result of either vascular ‘sludging’ or small-vessel thrombosis. Intestinal ischaemia and perforation due to thrombosis and coeliac artery stenosis have been described.

5.1.7 Haemocytopenias

Thrombocytopenia is a common haematological manifestation of APS, seen in around 25% of patients. It is rarely severe; platelet counts are usually $50\text{--}100 \times 10^9$, and bleeding is not a common problem. Haemolytic anaemia may be present in patients with APS and is sometimes associated with thrombocytopenia, the so-called Evans syndrome. Although a positive Coombs test is not rare in APS, haemolytic anaemia is not often seen (less often than thrombocytopenia). A small number of cases of marrow infarction have been described.

5.1.8 Musculoskeletal

Avascular necrosis of bone is most commonly of the femoral head, but also of other bones such as the navicular bone, and is a complication of APS, presumably as a result of ischaemia in vulnerable sites. Metatarsal fracture and other spontaneous fractures have been reported in the spine, ribs and elsewhere.

5.1.9 Endocrine system

Adrenal insufficiency is the most common endocrine manifestation and can be the presenting symptom of APS. A few cases of hypopituitarism and ovarian and testicular involvement have been reported.

Figure 10 : Left adrenal haemorrhage due to adrenal infarction in the antiphospholipid syndrome

5.2. Pregnancy

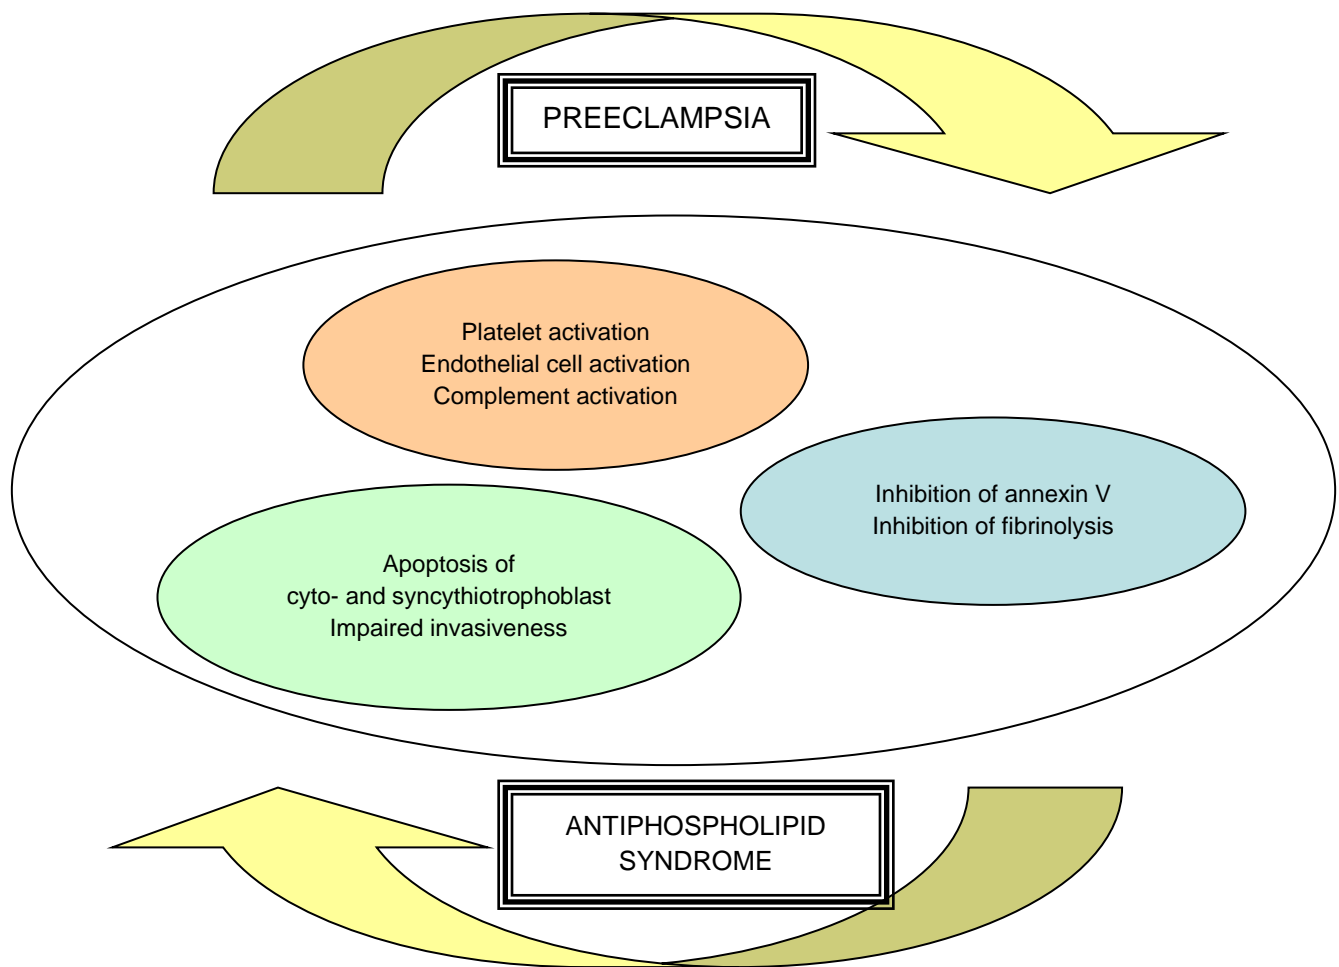

APS is frequently diagnosed following investigation for recurrent miscarriage, pregnancy morbidity being one of the major manifestations of the syndrome. In pregnancies that do not end in miscarriage or foetal loss, there is a high incidence of early onset pre-eclampsia, intrauterine growth restriction (IUGR), placental abruption and premature delivery (Branch *et al*, 2001; Lockshin *et al*, 2012*).

Pre-eclampsia has been reported in around one-third of patients with APS, being usually of early onset (before 34 weeks of gestation) and severe, and contributing to preterm delivery in these patients. Pre-eclampsia near term in the general population seems not to be associated with the presence of aPL. The risk of HELLP, a syndrome characterised by haemolysis, elevated liver enzymes, low platelets and proteinuria, is increased in APS with a wide range reported (0.66–10.6%). HELLP syndrome, pre-eclampsia and APS may share certain pathogenic mechanisms (figure 5). A peculiar feature is that the time of onset of HELLP in APS pregnancy is earlier than in the general obstetric population, occurring more frequently in the second trimester.

Placental insufficiency may also be manifested by foetal growth restriction, which is found in about 30% of patients with APS. Foetal distress has been reported in up to 50% of the offspring, although its association with aPL has not been confirmed. Pre-eclampsia and foetal growth restriction are responsible for the preterm delivery occurring in around 30% of pregnant women with APS.

Placental pathology may show extensive infarction, necrosis and thrombosis. However, these histological abnormalities are non-specific and are not always present in the placenta of women with APS. Thrombotic placental pathology is not specific for APS and pregnancy outcome is often unrelated to it.

Figure 5. Pathogenic mechanisms of pre-eclampsia and antiphospholipid syndrome. (Modified from Tincani et al, Nat Rev Rheumatol 2009;5:382–90.)

5.3 Pregnancy loss

Women with aPL have an unusually high proportion of pregnancy losses within the foetal period (≥ 10 weeks of gestation), in contrast with unselected women with sporadic or recurrent miscarriage, in whom the pregnancy losses occur more commonly in the pre-embryonic period (< 6 weeks of gestation) or the embryonic period (6–9 weeks of gestation). The prevalence of aPL in the general obstetric population is low ($< 2\%$), so universal screening is not warranted. However, any woman with a history of three or more first trimester miscarriages should be tested for these antibodies, once other causes have been excluded (chromosomal abnormalities, uterine anomalies, luteal phase insufficiency, cervical infections and thyroid hormone dysfunctions).

6. Catastrophic APS

Catastrophic APS (CAPS) is a life-threatening situation that develops in $< 1\%$ of patients with APS. CAPS discloses the APS in about 50% of cases. It is characterised by thrombosis at multiple organ sites, occurring concurrently or over a short period of time in association with positive aPL tests. Ischaemia of the kidneys, lungs, heart and/or

brain is most frequent. Adrenal, testicular, intestinal, splenic, pancreatic or skin involvement has also been described. Typically, occlusion of small vessels occurs (thrombotic microangiopathy), resulting in symptoms related to dysfunction of the affected organs.

It is recognised that precipitating factors, such as infections, postpartum period and surgery, may contribute to the development of CAPS. Additional precipitating clinical features include malignancy, medication, anticoagulation withdrawal and SLE exacerbation. Cerebral involvement (mainly, stroke), cardiac involvement and infections are the main causes of death in patients with CAPS. Recurrence of CAPS in the same patient is unusual.

CAPS overall mortality rate has decreased in the past decade and is now around 30%. The prevention of CAPS is based upon the adequate management of the perioperative period when surgery cannot be avoided, the prompt treatment of infections and the education of patients with APS.

Preliminary classification criteria for CAPS have been validated after analysing data from an international registry of patients with this condition (CAPS registry), and an international task force has been updating evidence on the management of this dramatic and life-threatening condition (Cervera et al, 2011*).

7. Classification criteria for definite APS

The definition of APS has been discussed in several international meetings involving experts from different specialties (rheumatology, obstetrics, neurology, haematology, nephrology, etc).

In 1998, the preliminary classification criteria for APS were proposed at Sapporo, Japan. Classification for APS required at least one clinical manifestation together with positive tests for circulating aPL, including LA and/or aCL at medium-high levels, detected at least twice in a 6-week period.

In 2006 the classification criteria were updated (Miyakis et al, 2006*). Essentially, the clinical criteria remained unchanged; however, two important modifications were agreed: the time between two positive determinations was extended to 12 weeks, in order to ensure the detection of persistent antibodies only; and anti- β 2GPI, both IgG and IgM, were added to the laboratory criteria. IgA isotypes as well as antiprothrombin and antiphosphatidylserine/prothrombin antibodies continued to be excluded from the criteria, since the committee felt that evidence for their inclusion was insufficient (table 3).

Other important points raised by the committee were the following:

- In patients with autoimmune disorders (SLE and RA) it is possible to find aPL associated with typical APS clinical manifestations. The episodes of thrombosis are similar in 'primary APS' (without other connective tissue disease) and 'secondary APS' (with connective tissue disease). The revised international consensus statement eliminated the 'primary' versus 'secondary' distinction, because there are no differences in the clinical consequences of aPL among patients in these two categories.

The new proposal is that patients with 'primary APS' should be described simply as having APS, and the term 'secondary APS' be replaced with APS together with specific mention of the autoimmune disorder with which it is known to be associated (i.e., APS and SLE).

- In patients with thrombotic events, it is strongly recommended to assess the presence of additional risk factors, either inherited or acquired, in order to better establish the role of aPL in the genesis of the thrombosis.
- Multiple aPL positivity is associated with a more severe course of the disease, increasing the rate of thrombosis and pregnancy morbidity; therefore, it is recommended that patients are tested for all three criteria tests, in order to distinguish triple positive patients from those with a single positive test.

8. Management of APS

Management of APS means prophylaxis. aPL are risk factors for thrombosis and pregnancy morbidity, therefore in carriers, occurrence of a first episode (primary prophylaxis) or recurrence (secondary prophylaxis) should be prevented. In the absence of solid guidelines derived from clinical trials (which are few in the field of APS), management of APS is still controversial and experts from different fields are trying to develop evidence-based recommendations. Management of patients with APS/aPL carriers should take many different aspects into consideration and provide a treatment tailored to the individual (Ruiz-Irastorza et al, 2011).

8.1 Management of thrombosis-free aPL-positive subjects (primary thromboprophylaxis)

aPL carriers, who can be either asymptomatic individuals or patients with SLE or other systemic autoimmune diseases, and women with obstetric APS need only to be protected against their first thrombotic event. The annual incident thrombosis risk is estimated to be no higher than 3.8%, on the basis of a few studies that also included patients with SLE.

The following recommendations should be considered:

- Any subject with aPL should strictly monitor and control modifiable vascular risk factors (hypertension, diabetes mellitus, obesity, cigarette smoking, high cholesterol, etc).
- In high-risk situations (surgery, post partum, long-lasting immobilisation) subjects should receive adequate thromboprophylaxis (eg, low molecular weight heparin (LMWH)).
- aPL asymptomatic carriers (on two or more occasions at least 12 weeks apart) and patients with obstetric APS may receive low-dose aspirin (eg, 100 mg/day) or no treatment (if no other risk factor is present).

- Patients with SLE or other autoimmune disorders (who have increased cardiovascular risk owing to the disease) should receive low-dose aspirin and/or hydroxychloroquine (a drug that has antiaggregant properties and was shown to be protective against the development of thrombosis).

8.2 Management after thrombotic episode (secondary thromboprophylaxis)

Based on current knowledge, which largely comes from retrospective studies and very few prospective, randomised trials, patients with definite APS should be treated with long-term anticoagulation.

For venous events the suggested target for the international normalised ratio (INR) is 2.0–3.0, while it is suggested that arterial events should be managed with high-intensity oral anticoagulation (INR = 3.0–4.0). However, new recommendations take into account both the clinical and the immunological profile of patients and suggest that a subgroup of patients could be treated less aggressively or for shorter periods (according to management in the general population). These are the patients with single positivity for aCL or anti- β 2GPI, preferentially at low titre, who had experienced thrombosis in the setting of reversible triggers.

Recurrence is not infrequent in patients with APS. Physicians may treat the recurrence by either increasing the intensity of anticoagulation or, if already at high intensity, adding low-dose aspirin. They must be aware, however, that the risk of bleeding is increased. An alternative strategy might be the use of immunomodulatory agents such as hydroxychloroquine and statins.

The role of steroids and immunosuppressive drugs in the treatment of patients with aPL and thrombosis is uncertain. Such drugs have severe side effects when given for prolonged periods, and aPL are not always suppressed by these agents. Furthermore, some series of patients with APS have shown that glucocorticoids and immunosuppressive drugs, prescribed to control lupus activity, did not prevent further thrombotic events. The use of these drugs is probably justified only in patients with CAPS. In this rare but life-threatening condition, the combination of anticoagulation, steroids and plasmapheresis or intravenous immunoglobulins is recommended. For CAPS and other severe manifestations, such as refractory thrombocytopenia, the use of B cell target therapies may be considered based on anecdotal reports of success (Berman et al, 2013; Erkan et al, 2014*).

Finally, management of pregnancy in these women is important (see next section and the online in-depth discussion).

8.3 Management in adverse pregnancy history (see also the online in depth discussion)

Pregnancy complicated by APS requires expert care and a team approach by APS-devoted physicians (obstetricians, rheumatologists, haematologists, etc). Patients with APS should undergo preconceptional assessment and counselling (see the online in-depth discussion). A detailed medical and obstetric history

should be obtained, and the presence of significant levels of aPL should be confirmed. The patient should be informed of the potential maternal and obstetric problems, including foetal loss, pre-eclampsia, HELLP syndrome, foetal growth impairment, preterm delivery and thrombosis or stroke.

The pharmacological management of pregnancy in women with APS is the subject of much debate (de Jesus et al, 2014*). It has included prednisone and aspirin, aspirin alone, low-dose aspirin (LDA) and heparin, intravenous immunoglobulins and even supportive care alone. Randomised controlled trials are few, small and have contradictory results. They showed that the effect of high-dose glucocorticoids on pregnancy outcome was no better than that of aspirin/heparin, while more side effects were seen (gestational diabetes, hypertension and infection as well as prematurity and foetal growth restriction). Treatment with LMWH plus LDA achieved 80% of live births, with few maternal complications in the European Registry on Obstetric Antiphospholipid Syndrome (Alijotas-Reig et al, 2015).

The management of pregnancy in APS may comprise the following situations:

- Women with 'definite' APS (according to the criteria): randomised controlled trials and systematic review of the literature support the combined treatment with LDA and LMWH as the most effective in preventing foetal loss. This will also protect the mother from thrombosis risk. However, 20% of pregnancies still have a negative outcome despite conventional treatment. An international multicentre case–control study of pregnancies prospectively followed up identified the following as negative prognostic factors: the association of APS with autoimmune diseases (particularly SLE), a history of both thrombosis and pregnancy morbidity, and triple aPL positivity (LA, aCL, anti- β 2GPI). This was confirmed in a recent prospective study, LA being associated with the worst obstetrical prognosis (Lockshin et al, 2012*). The management of these 'difficult cases' has not yet been standardised. There are multiple options—for example, increasing the anticoagulation dose or immunomodulation (glucocorticoids, hydroxychloroquine, intravenous immunoglobulins, plasmapheresis).
- Women with 'incomplete' APS (obstetric history not fulfilling criteria) or asymptomatic aPL carriers (without any clinical manifestation of APS): there is no codified treatment in these cases. However, treatment with LDA and/or LMWH could be given, based on a personalised approach (and with the additional goal of protecting the mother from thrombosis risk).
- Women with APS and previous thrombosis: the mother should be protected against the risk of recurrence; therefore a full anticoagulation during pregnancy is warranted. Most women will be taking warfarin and should be informed about the embryotoxicity of this drug. The strategy might be to stop warfarin as soon as the pregnancy test is positive, switching to LMWH and LDA. After delivery, warfarin can be resumed, as it is not contraindicated during breast feeding.

- Primary prevention of a first thrombotic event: women with pure obstetric APS, and asymptomatic carriers, should be protected against their first thrombosis. Puerperium is a high-risk period, so LMWH in a prophylactic dose is recommended for 6 weeks post partum. In addition, women should be screened for traditional cardiovascular risk factors (hypertension, dyslipidaemia, diabetes mellitus, etc) and informed they should avoid smoking, a sedentary lifestyle and the use of oestrogen-containing contraceptives.
-

SUMMARY POINTS

- Antiphospholipid syndrome (APS) is a complex systemic autoimmune disease.
- The clinical hallmarks are thrombosis and pregnancy morbidity, but multiple organs may also be affected.
- The diagnosis of APS is defined by the presence of antiphospholipid antibodies (aPL). However, aPL testing is affected by lack of standardisation despite international efforts, so the laboratory definition of APS is unresolved.
- The pathogenesis of APS is multifactorial and involves inflammatory pathways. aPL are risk factors for APS: a 'second hit' (triggering factor) is usually necessary for the development of aPL-mediated damage.
- Management of APS means prophylaxis. aPL carriers should be prevented from their first thrombotic event or pregnancy loss; patients who have already had an APS-related event must be protected against recurrence.
- International committees are working on several different topics to promote research on APS and produce evidence-based indications for the diagnosis, management and treatment of APS.

Pregnancy related problems in rheumatic diseases, including the antiphospholipid syndrome

Rebecca Fischer-Betz, Magdalena Siekierka-Harreis, Nathalie Costedoat-Chalumeau

A previous version was coauthored by Gaëlle Guettrot-Imbert, Nathalie Costedoat-Chalumeau, Angela Tincani

IN-DEPTH DISCUSSION I

Management of pregnancy in the antiphospholipid syndrome

1. Pregnancy counselling

Complications during pregnancy are common in antiphospholipid syndrome (APS) and include maternal thrombosis, recurrent spontaneous abortions before 10 weeks of gestation, and late adverse pregnancy outcomes such as foetal death, preeclampsia, foetal growth restriction, and pre-term birth. Even with optimal management the live birth rate for women with APS remains around 80% and adverse outcomes occur in a “refractory” 20-30% of cases. Pre-pregnancy and antenatal care in APS is crucial for minimising morbidity.

Preconception counselling is based on risk assessment in the individual patient. Important risk factors are concomitant autoimmune disease, history of both pregnancy morbidity and thrombosis, presence of lupus anticoagulant (LA) and triple positive aPL. Pregnancy should be discouraged in women with significant pulmonary hypertension due to the high risk of maternal death and postponed in the setting of uncontrolled hypertension or whenever a recent thrombotic event, particularly stroke, has taken place or in patients suffering from unexplained thrombosis recurrences.

2. General care of pregnancy in women with APS

A complete aPL profile, including repeated positive aCL and LA, must be available before planning pregnancy. Repetition of aPL tests can be helpful for assessment of maternal and foetal risks during pregnancy. A recent study (PROMISSE Study: Predictors of pRegnancy Outcome: bioMarkers In antiphospholipid antibody Syndrome and Systemic lupus Erythematosus) showed that LA is the main predictor for adverse pregnancy outcome, more than aCL and anti- β 2 GPI alone. Triple antibody positive women carry the highest risk for thrombosis and pregnancy complications. Women with thrombotic APS have worse obstetric outcomes than those with obstetric APS. Others risk factors for pregnancy failure are the association with SLE or other autoimmune diseases and a previous obstetrical complication. APS patients diagnosed on the basis of a single positive test and/or of history of early foetal loss alone were generally found to have successful pregnancies.

During pregnancy, women should be under the dual care of obstetricians and physicians specialising in APS. Monitoring should be undertaken more frequently as pregnancy advances, with prenatal visits every two weeks or more frequently if needed. At these visits blood pressure and urine protein should be measured, along with frequent ultrasounds to check foetal growth and well-being. Uterine artery Doppler flow studies at the 20th and 24th weeks of gestation are useful for predicting preeclampsia and placental insufficiency in APS.

3. Pharmacological management of APS in pregnancy

The goals of treatment in pregnant women with APS are to improve maternal and foetal-neonatal outcomes by minimising the risks of the recognised complications of APS, including maternal thrombosis, foetal loss, preeclampsia, HELLP syndrome, placental insufficiency and foetal growth restriction, and the need for

iatrogenic preterm birth. Heparin and low dose aspirin (LDA) are widely considered the current treatments of choice for APS in pregnancy. Heparin is initiated after a positive pregnancy test. Randomised trials have demonstrated that either the addition of intravenous immunoglobulins (IVIG) to heparin or IVIG alone offers no better outcomes. A subsequent Cochrane analysis concluded that IVIG was associated with an increased risk of pregnancy loss or premature birth compared to heparin and LDA.

Venous contention should be associated with the pharmacologic treatment.

New anticoagulants are easier to use and require less monitoring than traditional anticoagulants. However, experience from human pregnancy is limited to case reports and there are no publications on randomized controlled trials in APS. New Oral Anticoagulants should probably not be used so far. Several case reports showed healthy outcomes at exposure to the indirect factor-Xa inhibitor fondaparinux in pregnant women. Little is known about the safety of rivaroxaban, argatroban and dabigatran during pregnancy, and, therefore, their use is not recommended

a. Recurrent early (pre-embryonic or embryonic) miscarriage

Three randomised trials and one trial with consecutive treatment assignment have addressed pregnancy in APS patients with predominantly recurrent early miscarriage. In two trials, the proportion of successful pregnancies significantly improved adding unfractionated heparin to LDA. Two other randomised trials, both using low molecular weight heparin (LMWH) proved negative. It is noteworthy that the heterogeneity in the results was attributed to women receiving aspirin only. In addition, two studies found no differences in pregnancy outcomes when comparing unfractionated heparin with LMWH, both combined with aspirin. Among pregnancies progressing beyond 20 weeks gestation, maternal and foetal-neonatal outcomes were relatively benign, with the frequencies of foetal death, preeclampsia, severe placental insufficiency, and iatrogenic preterm delivery similar to those of the general obstetric population. On the other hand, several observational studies have reported 79% to 100% pregnancy success rates with LDA alone. Moreover, a recent meta-analysis has demonstrated a significant reduction of pregnancy complications among women at high risk for preeclampsia who were treated with anti-platelet agents (mostly aspirin).

Despite the obvious controversy raised by these trials, a 2005 Cochrane systematic review concluded that women with recurrent miscarriage and APS should be treated with a combination of unfractionated heparin 5000U subcutaneously twice daily and LDA, and recent expert guidelines recommend the combination of aspirin with either low-dose unfractionated heparin or LMWH. Preliminary results from the PROMISSE study indicate that the option of monotherapy with LDA cannot be discarded in this subgroup of women except for those who have a high-risk antibody profile.

b. Foetal death (>10 weeks of gestation) or prior early delivery (<34 weeks gestation) due to severe preeclampsia or placental insufficiency

The optimal treatment for women in this category is not defined by randomised trials. Most experts recommend LDA and either prophylactic, intermediate or curative dose heparin. The preponderance of data indicate that good pregnancy outcomes are achieved with heparin initiated in the early first trimester when a live embryo is discernible by ultrasound.

c. APS with thrombosis

For pregnant women with APS who have had a prior thrombotic event, LDA and therapeutic dose unfractionated heparin or LMWH anticoagulation are recommended. Vitamin K antagonists are teratogenic and should be avoided between the 6 and 12 weeks of gestation. Due to the risk of foetal bleeding thereafter, the use of warfarin after 12 weeks of gestation should only be undertaken in exceptional circumstances.

d. Refractory APS in pregnancy

There have been no properly designed studies to evaluate treatment modalities for the 20-30% of patients who fail to respond to LDA and heparin. Whether increase in the dose of anticoagulation or therapy with hydroxychloroquine, prednisone, azathioprine, IVIG or plasmapheresis is efficacious in the obstetric APS refractory to anticoagulant standard treatment is unanswered.

4. Labour and postpartum period

Thromboprophylaxis may represent a risk during labour, particularly, with the use of epidural anaesthesia. Stopping heparin 12 hours previous to and 12 hours after any interventional procedure is generally considered safe. Many anaesthesiologists would also require a minimum of 3-7 days without aspirin to perform a spinal tap. Several prospective studies of patients on LDA have not found an increased risk for epidural hematoma after epidural anaesthesia. According to recommendations, epidural anaesthesia should be realized in women taking LDA providing some conditions:

- Absence of any anticoagulant therapy before the spinal tap
- Absence of associated haemostasis disorders
- Avoid using medication which could interfere with haemostasis
- Close and regular neurologic monitoring after the spinal tap

Antithrombotic coverage of the postpartum period is recommended in all women with APS and also positive aPL, with or without prior thrombosis. Those with previous thrombosis would need long-term anticoagulation,

and we prefer switching the patient to warfarin, as soon as she is clinically stable after delivery. In cases of no previous thrombosis, the recommendation is for prophylactic dose unfractionated heparin or LMWH therapy for 6 weeks after delivery. Both heparin and warfarin are safe for nursing mothers. As pregnancy, heparin, and breastfeeding can all reduce bone mineral density, taking additional calcium 1000mg and vitamin D 800 IU daily can lower the occurrence of osteoporosis.

Although there have been suggestions that aPL may cause failure of in-vitro fertilisation (IVF), a literature review of 16 studies has found no association. Nevertheless, the high exposure to oestrogens during IVF causes a high risk of maternal thrombosis and it would be advisable to use prophylactic heparin and aspirin during this time if the woman has aPL.

Table 1 Recommendation for management during pregnancy

Antiphospholipid antibodies * without thrombosis without adverse pregnancy outcome in history:	
* triple positive, significantly and persistently elevated	Low dose aspirin (LDA): 100 mg/d
Antiphospholipid syndrome without thrombosis (exclusively obstetric complications) in history:	
Recurrent early miscarriage (< 10 WoG)	LDA 100 mg/d (pre-conception) <i>alone or in combination</i> with LMWH in <i>prophylactic</i> doses when preg. test positive
Foetal death (>10. WoG) or previous early delivery (<34 WoG) due to severe pre-eclampsia or placental insufficiency	LDA 100 mg/d (pre-conception) in combination with LMWH in <i>prophylactic</i> doses when preg. test positive
Antiphospholipid syndrome with thrombosis in history*:	
Without previous anticoagulation (coumadine)	LDA 100 mg/d (pre-conception) in combination with LMWH in <i>prophylactic</i> doses when preg. test positive LMWH may be increased in 2 nd and 3 rd trimester
With previous anticoagulation (coumadine)	Change to LMWH in <i>therapeutic</i> doses, + LDA (100 mg/d) at the latest with positive preg. test
During pregnancy in addition: control of blood pressure, proteinuria, weight from 16. - 20. WG monthly control of foetal growth and placental blood flow	
Post-partum:	
For 6 weeks heparin (LMWH), then therapy according to indication (APS) (i. e. LDA or anticoagulation). Also: prophylaxis for osteoporosis with heparin / LMWH; Compression stockings, gymnastics	

**Usually these patients would be anticoagulated!*

Pregnancy related problems in rheumatic diseases, including the antiphospholipid syndrome

IN-DEPTH DISCUSSION II

Preconception counselling

Pregnancy in women with a systemic disease must be planned to reduce the risk of maternal and foetal complications. A consultation for preconception counselling is therefore an essential prerequisite to such a pregnancy. Several key points will be discussed during this visit:

1. Screening of contraindications to pregnancy:

Contraindications to pregnancy are now rare. They are principally active underlying disease or a recent flare at the time of the visit, especially in systemic lupus erythematosus (SLE). This contraindication is therefore generally transient. Moreover, damage such as organ failure, history of severe preeclampsia, or HELLP syndrome despite appropriate treatment can be contraindications to pregnancy and must lead the couple to envision other ways of becoming parents. Table 1 summarizes the principal contraindications.

Table 1: Principal contraindications to pregnancy: to discuss on a case-by-case basis with the couple and the different specialists.

Current or recent flare of the systemic disease
Corticosteroid dependency greater than 0.5 mg/kg/d
Pulmonary arterial hypertension
Uncontrolled hypertension
Heart failure with an ejection fraction less than 30%
Severe valve disease and in particular shrinkage of the mitral or aortic valves
Aortic dilatation greater than 50 mm
History of postpartum cardiomyopathy resulting in chronic heart failure *
Forced expiratory volume less than 50%
Treatment incompatible with pregnancy
± Creatinine clearance less than 40 ml/min**
Severe malabsorption

* Regardless of the severity of the heart failure.

** Creatinine clearance less than 40 ml/min is a relative contraindication to be discussed with nephrologists on a case-by-case basis.

2. Assessment of the risks:

- Potential repercussions of the systemic disease on the pregnancy

Situations at risk of complication include: a history of complications during any previous pregnancy, a recent flare (less than 6 months for SLE), a corticosteroid dosage greater than 10 mg daily, resultant chronic organ failure (cardiac, renal, and pulmonary in particular), hypertension, antiphospholipid antibodies or antiphospholipid syndrome (APS), in particular with a history of thrombosis (especially arterial), and/or anti-SSA or anti-SSB antibodies. Age greater than 40 years, multiparity, and diabetes are also risk factors for complications during pregnancy, even without any autoimmune disease.

- Potential repercussions of the pregnancy on the systemic disease

The principal potential repercussion is the risk of a flare of the underlying disease but also decompensation of disease-related organ failure.

For each disease, see the corresponding section in the course.

- Planning management

The treatment procedures and follow-up are determined at the visit of counselling, in order to plan an optimal multidisciplinary management (obstetricians, internists or rheumatologists, anaesthetists) and thus increase the likelihood of success. These procedures will be determined by the woman's clinical history and her laboratory and immunological profile.

Table 2 summarizes the laboratory tests to be performed for the preconception consultation.

Table 2: Laboratory tests for the preconception consultation

Complete blood count
ACT (activated clotting time)
Transaminases
Creatinine
Serology for HIV, hepatitis B, toxoplasmosis, and rubella
Urinary sediment: leukocyturia, haematuria
Urinary PCR (protein/creatinine ratio) or 24-h urinary protein
LDH (lactate dehydrogenase), haptoglobin, GGT (gamma glutamyl transpeptidase), serum uric acid
TSH (thyroid-stimulating hormone), thyroid peroxidase antibodies
Lupus anticoagulant, anticardiolipin and anti-β2GP1 antibodies (± TPHA-VDRL) *
Anti-SSA and anti-SSB antibodies
According to the underlying disease: anti-dsDNA antibodies, complement C3, ANCA (anti-neutrophil cytoplasmic antibody, Scl70 antibodies, anti-RNA polymerase III

**The higher risk-profiles are the triple positivity (3 antibodies positive) followed by lupus anticoagulant.*

3. Interview with the couple

The preconception counselling visit allows the doctor to explain to the couple the potential risks for the baby and for the mother. If the doctor is recommending to avoid or postpone pregnancy, this visit allows him or her to explain both the reasons for this to the couple and the objectives to be reached before pregnancy can be medically authorized (for example, better disease control in the case of a recent renal flare).

4. Adaptation of treatments to pregnancy

Finally, if pregnancy is envisioned, the drugs advised against or forbidden during pregnancy must be stopped and, if necessary, replaced. Safety of treatment during pregnancy should be addressed and explained in order

to reassure the mother. Folic acid supplementation is routine, essential in women previously treated by methotrexate or with haemolytic anaemia, even well compensated, to limit the risk of neural tube defects. Adequate calcium and vitamin D intake is desirable, in particular in women receiving corticosteroid therapy and heparin together. Bisphosphonates prescribed before pregnancy should be stopped. Calcium supplementation should target 1500 mg/d, including food intake and pharmacological supplementation (Fardelonne's formula for calcium intake available on line: <http://www.grio.org/calcul-apport-calcique-quotidien.php>).

This consultation is also an ideal time to approach the difficulties of adherence to treatment.

5. Updating vaccinations

Vaccinations should be updated if necessary: rubella if serology is negative, unless strong immunosuppression is present (biologics or immunosuppressive agents, corticosteroids up to 10 mg per day for more than 15 days), whooping cough if the last booster date was more than 10 years earlier (verify the future father's vaccination at the same time), and influenza depending on the time of year.

6. Specific cases

- SLE:

During pregnancy of women with SLE, the previous treatment is usually continued: hydroxychloroquine, even corticosteroids, ideally not exceeding 10 mg/d. When an immunosuppressant is necessary, azathioprine is preferred.

- Aspirin

Aspirin at a dose that inhibits platelet aggregation is indicated when there is pre-existing kidney damage, hypertension, a history of preeclampsia, antiphospholipid antibodies, or when the disease is known to increase the risk of foetal damage (foetal growth restriction, small for gestational age, preterm delivery). Aspirin has to be started before conception (or at the latest in the first trimester).

- Antiphospholipid antibodies

In addition, heparin, at a preventive or curative dosage, should be discussed if the laboratory results reveal antiphospholipid antibodies and the woman has a history of thrombosis and/or obstetric complications and/or high-risk antibody profile (3 tests positive at high titer, lupus anticoagulant). Table 3 describes appropriate management according to the different clinical situations. Wearing support stockings is usually recommended. Ideally, the prescription should be given to the patient at the preconception consultation, especially if she is treated with oral anticoagulants: this will allow her to switch to heparin as soon as she knows she is pregnant.

Table 3: Suggested management for antiphospholipid antibody syndrome or antiphospholipid antibodies.

	Treatment during pregnancy
Positive antiphospholipid antibodies with no history of thrombosis or obstetric complications	Aspirin alone (100 mg/d). If a lupus anticoagulant is present and/or in case of multiple positivity, preventive LMWH could/should be considered. Preventive LMWH in the postpartum period (for 6 weeks), and then aspirin to be considered for the long-term.
APS with a history of thrombosis	Low-dose aspirin (100 mg/d) combined with a curative dosage of LMWH (e.g., enoxaparin 100 IU anti-Xa/kg every 12 hours, subcutaneously)**. Regular adaptation to anti-Xa activity can be discussed. Resumption of a vitamin K antagonist in the postpartum period*.
APS without a history of thrombosis but with recurrent spontaneous miscarriages	Low-dose aspirin (100 mg/d) associated with LMWH (enoxaparin 0.4 ml daily, subcutaneously***). Preventive LMWH in the postpartum period (for 6 weeks), and then aspirin for the long-term.
APS with no history of thrombosis but with a history of intrauterine death, preeclampsia, HELLP syndrome, or other manifestations of placental insufficiency	In the absence of previous treatment: Low-dose aspirin (100 mg/d) combined with LMWH (enoxaparin 0.4 ml daily, subcutaneously). Despite previous treatment (or sometimes from the start): low-dose aspirin (100 mg/d) combined with a curative dosage of LMWH (e.g., enoxaparin 100 IU anti-Xa/kg every 12 hours subcutaneously). Regular adaptation to anti-Xa activity can be discussed. Preventive LMWH in the postpartum period (for 6 weeks), and then aspirin for the long-term.

APS: antiphospholipid syndrome, HELLP: Haemolysis, Elevated Liver enzymes, Low platelets, LMWH: low-molecular-weight heparin.

* Only warfarin is authorized among the vitamin K antagonists for women who are breastfeeding.

** In the particular case of women with APS with a history of thrombosis but who are no longer taking a vitamin K antagonist (previous thrombosis, either distal or with a precipitating factor that is no longer present), it is possible to give enoxaparin at a lower dosage. Moreover, some replace enoxaparin-Lovenox® at a curative dose with tinzaparin-Innohep®, for example.

*** In the presence of a high-risk antibody profile or in case of obesity, higher dose of LMWH might be used.

7. Planning monitoring

Monitoring will be adapted to the underlying maternal disease and to the antibodies present (see course).

For SLE, which remains the disease most sensitive to the risk of flares and complications during pregnancy, monitoring should be regular and adapted to the maternal and obstetric history. It is generally monthly, or

even more frequent if necessary, at closer intervals during the last trimester, and continues during the postpartum period. Table 4 summarizes these monitoring rules.

Table 4: Monitoring the pregnancy of a woman with SLE

Clinical	Weight, blood pressure, Urinary dipstick +++
	Hypertension defined by SBP \geq 140 mmHg or DBP \geq 90 mmHg
	Joints
	Cutaneous lesions
	Oral ulcers
	Alopecia
	Oedema of the lower limbs
	Chest pain, severe epigastric pain
	Headaches, tinnitus, phosphines
Laboratory results	Complete blood count, platelets
	Serum creatinine level and estimated GFR by MDRD formula
	Serum uric acid
	Transaminases
	Haptoglobin
	Proteinuria: 24-hr collection or UPr/Cr fresh urine sample
	CH50, C4, C3
	Anti-DNA antibodies
	Blood glucose, K ⁺ especially for women with corticosteroid therapy
Ultrasound	Serology for toxoplasmosis, if negative initially
	Foetal ultrasound each trimester*
	If anti-SSA and/or anti-SSB antibodies: every two weeks between 16 and 24 WG or every week if sibling with neonatal lupus.
	If antiphospholipid antibodies or APS: Doppler around 20-22 WG (to be repeat if abnormal)
	If there is a risk of foetal growth restriction or preeclampsia: Doppler of the uterine and umbilical arteries at 20 weeks, to be repeated according to the need in case of abnormalities

SBP: systolic blood pressure; DBP: diastolic blood pressure; U Pr/Cr: urine protein-to-creatinine

For women with antiphospholipid antibodies, especially if there is an APS: monitoring must also be monthly, at closer intervals at the end of pregnancy for clinical and laboratory monitoring of the onset of preeclampsia or HELLP syndrome. Monitoring also includes ultrasonography, with a Doppler of the uterine and umbilical arteries at 20 weeks, to be repeated according to the need in the case of abnormalities (foetal growth restriction, a notch, increase in the resistance index, diminution of placental perfusion).

For women with anti-SSA and/or anti-SSB antibodies: because these antibodies expose the foetus to the risk of neonatal lupus, foetal cardiac ultrasound monitoring is currently recommended every two weeks between 16 and 24 weeks (every week if a previous foetus/child had congenital heart block). These recommendations may be alleviated in the future, if the absence of efficacy of fluorinated steroids is confirmed.

Systemic sclerosis

Roberto Giacomelli, Piero Ruscitti, Yannick Allanore

A previous version was co-authored by Jérôme Avouac, Yannick Allanore, Marco Matucci-Cerinic, Irene Miniati, Chris P. Denton

LEARNING OBJECTIVES

- Describe and explain the principal mechanisms of the pathogenesis of the disease
- Acquire the competence of making a diagnosis of the disease
- Knowing the main predictive factors for severity
- Describe and explain the main complications of the disease
- Investigate internal organ involvement through lab and instrumental examinations
- Evaluate the disease activity of the patients
- Prescribe an overall treatment of the disease
- Prescribe a treatment specific for target organs

I Introduction

Systemic sclerosis (SSc) is a connective tissue disease characterized by fibrosis of the skin and internal organs, pronounced alterations in the microvasculature and frequent cellular and humoral immunity abnormalities. SSc is part of a more extensive group of diseases called scleroderma spectrum (table 1) (Subcommittee for scleroderma criteria, 1980).

Table 1: The scleroderma spectrum of disorders

Localized scleroderma	Morphea
	Linear scleroderma
	En coup de sabre
Systemic sclerosis	Limited cutaneous systemic sclerosis
	Diffuse cutaneous systemic sclerosis
	Systemic sclerosis <i>sine scleroderma</i>

The distinction between localized scleroderma and systemic sclerosis is based on clinical presentation and on visceral involvement. Localized scleroderma is restricted to fibrotic involvement of the skin and subcutaneous tissues, while SSc (“systemic scleroderma”) affects also internal organs. There are some histopathological, pathogenetic and serological features common to localized and systemic forms of scleroderma, suggesting some similar pathogenic mechanisms. Therefore, a skin biopsy is not indicated to make a diagnosis or try to differentiate localized versus systemic disease. However, conversely to what is seen in lupus, the progression of localized scleroderma toward systemic sclerosis is exceptional and patients with morphea should be reassured concerning the risk of systemic involvement. This suggests some additional risk factors and/or biological actors driving the disease toward the systemic feature.

In the absence of one diagnostic test proving the absence or presence of SSc, some sets of classification criteria have been developed. Classification criteria are not similar to diagnostic criteria but they mirror the list of criteria that are used for making the diagnosis. Therefore, the purpose of a classification aims at including for research patients who have the disease as determined through a uniform definition. Until 2013, the standard classification criteria for SSc were the 1980 preliminary criteria for the classification of SSc, developed by the American College of Rheumatology. However, they had been developed using patients with longstanding SSc and mainly to classify patients with diffuse skin involvement. Indeed, by example, auto-antibodies and capillaroscopy were not taken into account despite the accumulating amount of work reported on these parameters. LeRoy et al proposed in 1988 a new set of criteria that included all clinical features, autoantibodies, and capillaroscopy. This resulted in a pragmatic sub-classification in limited cutaneous and

diffuse cutaneous (measured at the peak of skin extent) which remains very helpful as associated with various outcomes and organ involvement in these 2 subsets.

Limited cutaneous systemic sclerosis (lcSSc) is defined by skin involvement only distal to the elbows and knees, while diffuse cutaneous systemic sclerosis (dcSSc) is characterized by presence of skin thickening proximal to the knees and elbows. SSc sine scleroderma refers to patients who demonstrate vascular and serological features of SSc without any skin involvement (Diab et al, 2014). This sub-setting is important to know and use in clinical practice. It has an important impact with regards to the profile of the SSc patients, the risk of organ involvement and disease progression. Limited cutaneous disease is usually considered as a milder form with slow progression of skin involvement and rather late visceral complication (after 10-15 years) mainly exposing to pulmonary arterial hypertension and gastro-intestinal disease with malabsorption. Therefore, a long and sustained follow-up is mandatory although the disease may be seen as not severe at the beginning. SSc sine scleroderma has a very close profile to the one observed in lcSSc. The diffuse cutaneous form could be regarded as the opposite with fast progression of skin sclerosis within weeks / months and concomitant organ injuries, mainly lung, heart, kidney, before a plateau reached in about 5 years and thereafter a slow spontaneous regression of skin fibrosis. These patients need a very scrupulous follow-up in the first years with regular appointments and can be partly reassured once the first 5 years are over.

However, because of the insufficient sensitivity of 1980's criterial, the ACR and the EULAR promoted a joint proposal for new classification criteria for SSc. The aims were to develop criteria that 1) encompass a broader spectrum of SSc including patients whose disease is in the early stage as well as those in the late stage; 2) include vascular, immunologic, and fibrotic manifestations; 3) are feasible to use in daily clinical practice; and 4) are in accordance with criteria used for diagnosis of SSc in clinical practice. The updated classification is detailed in Table 2 (Van den Hoogen, 2013).

CREST (calcinosis, Raynaud's phenomenon, oesophageal dysmotility, sclerodactyly, and telangiectasia) syndrome is an outdated term for lcSSc and should not to be used as a synonym for limited SSc because many patients with lcSSc do not develop all the features of CREST. This acronym does not recognise important complications of this subset including pulmonary arterial hypertension, mid-gut disease and lung fibrosis. SSc can also overlap other autoimmune diseases such as systemic lupus erythematosus, dermatomyositis and rheumatoid arthritis (overlap syndromes). More and more evidence also show that multiple autoimmune disease can coexist in a single patient; this has been measured at about 25% with thyroiditis or Sjögren's syndrome being the most commonly associated autoimmune disease with SSc. Out of 3240 registered patients in the German network, 10% were diagnosed as SSc-overlap syndrome (two connective tissue diseases at the same time). The main characteristics of this subset were earlier and more common musculoskeletal involvement than patients diagnosed as lcSSc or dcSSc. The onset of lung fibrosis and heart involvement in SSc-overlap patients was significantly earlier than in patients with lcSSc but occurred later than in patients with

dcSSc. Oesophagus, kidney and PH progression was similar to lcSSc patients, whereas dcSSc patients had a significantly earlier onset. These data suggest that the concept of SSc-overlap syndrome might be regarded as a separate SSc subset, distinct from lcSSc and dcSSc (Moinzadeh et al, 2015).

Table 2: Systemic sclerosis 2013 ACR/EULAR classification

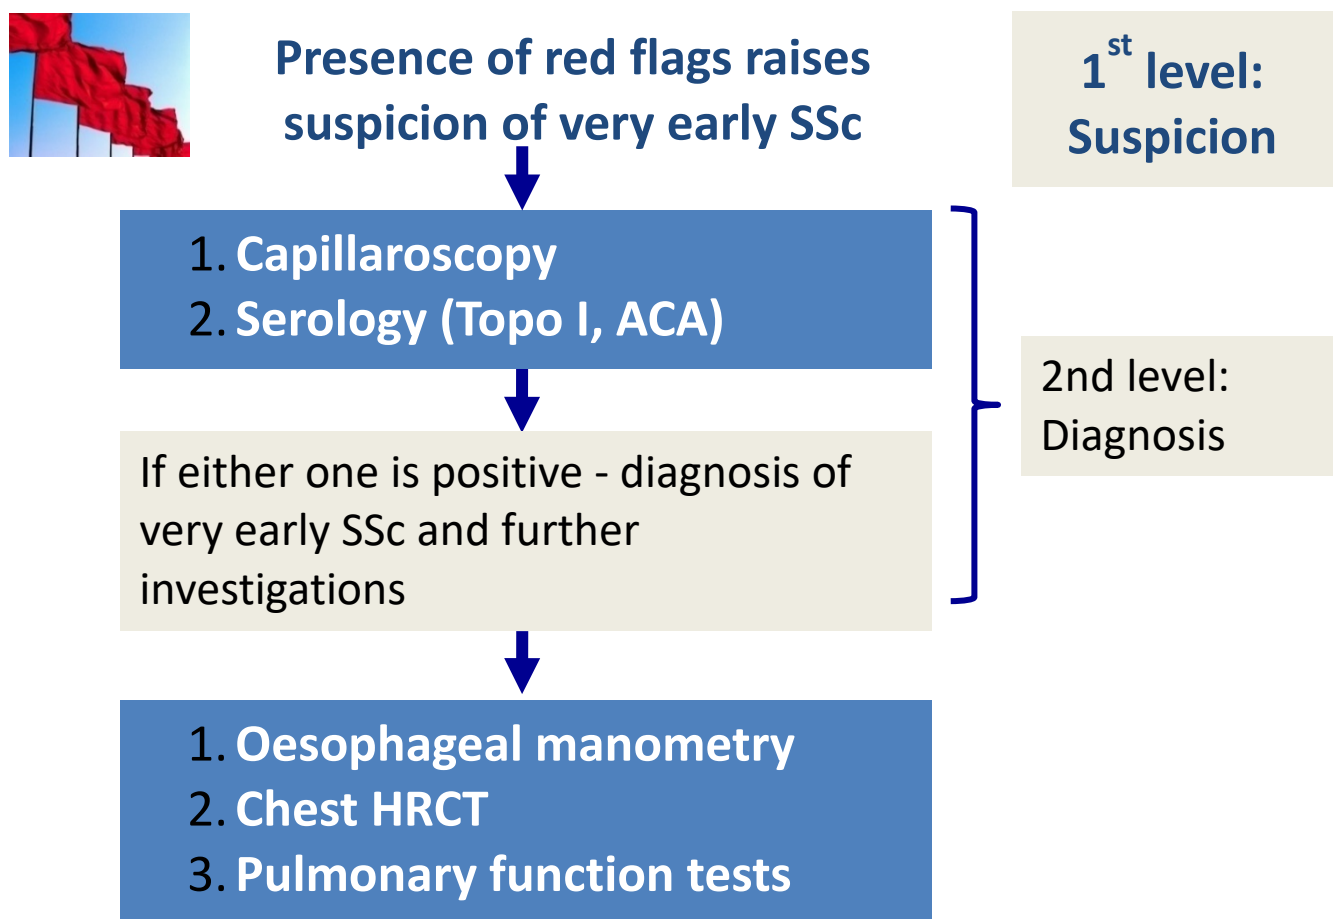

Item	Sub-item(s)	Weight/ Score
Skin thickening of the fingers of both hands extending proximal to the metacarpophalangeal joints (<i>sufficient criterion</i>)	–	9
Skin thickening of the fingers (<i>only count the higher score</i>)	Puffy fingers	2
	Sclerodactyly of the fingers (distal to the metacarpophalangeal joints but proximal to the proximal interphalangeal joints)	4
Fingertip lesions (<i>only count the higher score</i>)	Digital tip ulcers	2
	Fingertip pitting scars	3
Telangiectasia	–	2
Abnormal nailfold capillary	–	2
Pulmonary arterial hypertension and/or interstitial lung disease (<i>maximum score is 2</i>)	Pulmonary arterial hypertension	2
	Interstitial lung disease	2
Raynaud's phenomenon	–	3
SSc-related autoantibodies (anticentromere, anti-topoisomerase I [anti-Scl-70], anti-RNA polymerase III) (<i>maximum score is 3</i>)	Anticentromere	3
	Anti-topoisomerase I	
	Anti-RNA polymerase III	

These criteria are applicable to any patient considered for inclusion in an SSc study. The criteria are not applicable to patients with skin thickening sparing the fingers or to patients who have a scleroderma-like disorder that better explains their manifestations (e.g., nephrogenic sclerosing fibrosis, generalized morphea, eosinophilic fasciitis, scleroderma diabeticorum, scleromyxoedema, erythromyalgia, porphyria, lichen sclerosis, graft-versus-host disease, diabetic cheiroarthropathy). (a) The total score is determined by adding the maximum weight (score) in each category. Patients with a total score of ≥ 9 are classified as having definite SSc.

Leroy and Medsger proposed some years ago potential criteria for the classification of early SSc, defined by patients with features of SSc who do not fulfil the ACR or LeRoy classification criteria for SSc, consisting of Raynaud's phenomenon, scleroderma-type nailfold capillary pattern and scleroderma selective antibodies (LeRoy et al, 2001). Recently EUSTAR (European League Against Rheumatism Scleroderma Trial and Research Group) has proposed new criteria, refining the previous ones, for a very early diagnosis of SSc (VEDOSS) that are represented by the presence of the three red flags (Raynaud's phenomenon, puffy fingers and antinuclear antibodies (ANAs) positivity) plus disease-specific autoantibodies (anticentromere Ab (ACA) or anti-topo I Ab (Scl70)) or microvascular alterations detected by nailfold videocapillaroscopy. These criteria have been selected through a large Delphi technique among experts and is the basis of a large and ambitious project

aiming at the validation of VEDOSS criteria through the follow-up of a cohort of about 1000 individuals (Avouac et al, 2011) (figure 1). The aim of the VEDOSS criteria is to facilitate SSc diagnosis at the earliest possible stage so that early screening for pre-clinical internal organ involvement can be implemented. Very preliminary data have recently showed that puffy finger could be a critical criterion of very early disease (Minier et al, 2013). In line with the “window of opportunity” highlighted in rheumatoid arthritis, early diagnosis in SSc is essential for starting appropriate treatment aimed at blocking disease evolution or progression and huge efforts are made on the early steps of the disease to try to identify very early patients and predictors of poor outcomes.

figure 1: Flow chart for patients in whom the very early diagnosis of SSc should be considered is proposed. Red flags should trigger the differential diagnosis of SSc and guide the general practitioner to send the patient to the referral centre where capillaroscopy and specific autoantibodies are ordered and the diagnosis of very early SSc is made. HRCT, high resolution CT; PFT, pulmonary function tests. (Ann Rheum Dis. 2011;70(3):476-81.)

II Epidemiology

Available studies have reported divergent prevalence and incidence estimates of SSc in different areas of the planet. Lower estimates of prevalence (<150 per million) and of incidence (<10 per million per year) have been observed throughout northern Europe to Japan whereas higher estimates have been found in southern Europe, northern America and Australia (Barnes J et al, 2012).

SSc is an orphan disease and it seems to be more prevalent in the United States (276 cases per million adults) (Minier et al, 2013), than in Europe 80-150 cases per million adults (Czirjak et al, 2005).

The real prevalence of SSc has been probably underestimated because the mild disease remains often undiagnosed. The annual incidence of new cases has been reported from 1 to 20 cases per million (Allcock et al, 2004). SSc is three times more common in women than in men (Kettaneh et al, 2007). Several recent series estimate in different populations a prevalence of approximately 1 in 10000, with incidence rates about 1 in 100000 (figure 2)

Figure 2: Age-specific incidence of SSc by gender and race (Mayes et al, A&R 2003;48:2246)

Figure 3: Age of onset of the first non-Raynaud's symptom (% of patients) in male and female SSc patients throughout 11318 registered patients

The EUSTAR cohort has provided insight in gender effect by looking at 9182 SSc-patients, including 1321 males (Elhai et al, 2014). The figure 3 shows gender distribution according to age. In a cross-sectional approach, male gender was independently associated with a higher risk of diffuse cutaneous subtype (OR: 1.68, [1.45-1.94]; $p < 0.001$), a higher frequency of digital ulcers (OR: 1.28 [1.11-1.47]; $p < 0.001$) and pulmonary arterial hypertension (OR: 3.01 [1.47- 6.20]; $p < 0.003$). In a longitudinal part based on 4499 patients with follow-up (mean 4.9 ± 2.7 years), male gender was predictive of new onset of pulmonary arterial hypertension (HR: 2.70 [1.38-5.29]; $p = 0.004$) and heart failure (HR: 2.15 [1.03-4.48]; $p = 0.04$). It predicted deaths of all origins (HR: 1.48 [1.19-1.84]; $p < 0.001$), but did not significantly account for SSc-related deaths.

An epidemiological study performed in a southern region of Sweden (total population 1.2 million), reported that using the 1980 ARA criteria, the adult prevalence and annual incidence of SSc were 235 and 14 per 1 million inhabitants respectively. Applying the 2013 ACR-EULAR criteria, the corresponding figures were 305 and 19 per 1 million inhabitants. The use of the recent criteria resulted in 30-40% higher estimates of SSc prevalence and incidence and with a majority of lcSSc cases recognised selectively by the new criteria (Andréasson et al, 2014).

The prognosis of SSc remains poor but it is apparent that subsets of patients have very bad outcomes sometimes after a short time of disease duration and with impact on life expectancy whether some others will remain stable with a milder disease. A consideration regarding the prediction of outcomes is therefore a critical challenge and deciphering the factors that impact the prognosis of this highly polymorphic disorder is a challenge. Clearer views are emerging taking advantage of large large cohorts and with the standardization of follow-up of the patients and more precise definitions of organ damages. Predicting the disease is critical to

contribute to the evaluation of potential benefits and risks of the various old and new drugs that are under evaluation in SSc.

To focus on the final outcome that is mortality some efforts have been done to try to identify SSc patients with the highest risk. Indeed, EUSTAR promoted the evaluation of a simple prognostic model to predict 5-year survival in SSc throughout Europe (Fransen et al, 2011). The predefined prognostic model uses the following baseline variables: age, gender, presence of urine protein, erythrocyte sedimentation rate (ESR) and carbon monoxide diffusing capacity (DLCO). Data were available for 1049 patients of whom 119 (11%) died within 5 years after diagnosis. The prognostic model with age (OR 1.03), male gender (OR 1.93), urine protein (OR 2.29), elevated ESR (1.89) and low DLCO (OR 1.94) had an area under the receiver operating characteristic curve of 0.78. Death occurred in 12 (2.2%) of 509 patients with no risk factors, 45 (13%) of 349 patients with one risk factor, 55 (33%) of 168 patients with two risk factors and 7 (30%) of 23 patients with three risk factors (Table 3).

Table 3: A simple prognostic model using three disease factors to predict 5-year survival at diagnosis in SSc

No of risk factors	Total no of patients	No of patients deceased	Mortality%
0	509	12	2.2
1	349	45	12.9
2	168	55	32.7
3	23	7	30.4

Using an inception cohort of US Caucasian patients with early dcSSc (<2 years from the appearance of the first symptom) and a UK external replication cohort, 6 independent predictors of death at 5 years were identified. They include age at first visit, male gender, tendon friction rubs, gastrointestinal involvement, RNA polymerase III antibodies and anaemia (Domsic et al, 2016). This is a simple scoring system requiring only history, physical examination, and basic laboratory assessments.

These examples highlight the input of prospective cohorts and the ongoing works aiming at the risk stratification, which is highly, needed to better manage SSc patients. Autoantibodies targeting characteristic nuclear antigens are one of the hallmarks of SSc. The occurrence of different antinuclear antibodies (ANAs) is associated with distinct disease subtypes and with differences in disease severity, including extent of skin involvement, internal organ manifestation and also prognosis. For example and of most importance for clinical practice, the presence of anticentromere antibodies (ACAs) has been noted in association with PAH, anti-topoisomerase I (anti-topo I) antibodies in association with interstitial lung disease, and anti-RNA polymerase III (anti-RNAP III) antibodies in association with renal crisis. The main auto-antibodies, their frequencies and

associated features are summarised in Table 4 and the prevalence observed within EUSTAR cohort are shown in Figure 4.

Table 4: Main associated SSc auto-antibodies

Auto-antibody	Frequency (%)	Main clinical associations
Anti-centromere	30-40	LcSSc, PAH, older age at onset, other autoimmune disease
Anti-topoisomerase I	20-30	DcSSc, ILD, renal crisis, joint involvement
Anti-RNA pol III	1-10	DcSSc, renal crisis, GAVE, cancer
Anti-fibrillarin (U3RNP)	<5	DcSSc, PAH, musculo-skeletal
Anti-Th/To	<5	LcSSc, PAH
Anti-Pm-Scl	<5	Myositis
Anti U1RNP	<5	SSc overlap syndrome
Anti-Ku	< 5	SSc overlap syndrome and with muscular involvement

Figure 4: prevalence (% positive patients) of antinuclear antibodies in the EUSTAR cohort throughout 13996 registered SSc patients (Database extraction April 2017) (ANA: anti-nuclear; ACA: anti-centromere; TOPO: topo-isomerase; RNA poly III: RNA polymerase III)

The influence of ethnicity is a matter of concern in other connective tissue disorder like systemic lupus. A large monocentric study has been performed in the US (Gelber et al, 2013), showing that African American patients with SSc presented at a younger mean age than white patients (47 vs. 53 years; $p < 0.001$). Furthermore, two-thirds of white patients exhibited the limited cutaneous subset of disease, whereas the majority of African American patients exhibited the diffuse cutaneous subset ($p < 0.001$). In addition, African American patients experienced an increase in risk of mortality (relative risk 1.8; 95% CI, 1.4-2.2), after adjustment for age at disease onset and disease duration. Another recent large study from the US documented that the frequency of severe pulmonary fibrosis and related outcomes were higher in African Americans than in Caucasians even within some autoantibody subsets, particularly the subsets of patients who were positive for anti-topo I and anti-U1 RNP,

both of which are intrinsically associated with pulmonary fibrosis (Steen et al, 2012). Therefore, race is related to a distinct phenotypic profile having a trend toward more unfavourable outcomes in African Americans.

III Aetiology

Environmental factors have been proposed as possible causative factors (Bovenzi et al, 2004 ; Dospinescu et al, 2013). The most intensively described is silica dust, and many reports have initially detailed the illness in gold miners and coal miners exposed to crystalline silica. It is a disease determinant mainly in male systemic sclerosis, with disease features including a long latency and clinical characteristics indistinguishable from idiopathic disease. Cross-sectional 'current' occupational data underestimate cumulative occupational silica exposure which is not easy to measure / quantify.

In more recent years, SSc and scleroderma-like illness have been associated with exposures to other substances in industrial settings (Dospinescu et al, 2013 ; Diot et al, 2002 ; Garabrant et al, 2003). Examples include vinyl chloride used in the manufacturing of plastics, epoxy resins, and many solvents. Some of the solvents that have been implicated are trichloroethylene, benzene, xylene, and toluene. Among subjects with occupational exposure to solvents, men are at higher risk than women for the disease. The presence of microchimerism (Jimenez et al, 2005), infectious agents such as cytomegalovirus (Hamamdzc et al, 2002 ; Lunardi et al, 2006) and the inherent propensity for oxidative stress with associated generation of free radicals (Herrick et al, 2001) are also candidate factors that might contribute to disease progression.

III.1 Pathogenesis and Genetic predisposition

Pathogenesis of SSc is very complex and at present there is no unifying theory that may explain all its aspects. However, there are three main mechanisms responsible for the clinical and pathologic manifestations of SSc: 1) Vascular damage, principally of microcirculation; 2) Immune system activation/Auto-immunity/Inflammation, 3) Fibrosis.

The role of genetic factors is supported by the observation of familiar clustering of the disease; the high frequency of occurrence of other autoimmune disorders and autoantibody positivity in SSc family members; differences in SSc prevalence and clinical manifestations among different ethnic groups and the increased prevalence of certain human leukocyte antigen (HLA) and major histocompatibility complex (MHC) in various ethnic populations with SSc (Johnson et al, 2002 ; Allanore et al, 2010).

Multi-centre and trans-national efforts have allowed the building of large cohorts, which are mandatory to investigate the genetic component in complex disorders. The most convincing results to date have been obtained for the autoimmune component, with replication in large studies identifying HLA, IRF5, TNFAIP3 and STAT4 as the principal genes involved. As in many multi-factorial diseases, the presence of several polymorphisms in a given individual probably contributes to the risk of the disease, with each polymorphism

having only a minimal effect on its own. Several of these genes are already well-established risk factors for other autoimmune diseases, raising the possibility of shared autoimmunity (Allanore et al, 2010). However, this highly complex puzzle is not yet complete and the so-called missing heritability is still challenging. These results raising the critical role of autoimmunity is nonetheless a major paradigm shift in a disease which was until recently considered only as a fibrotic condition driven predominantly by fibroblast dysfunction. In contrast to genetic alterations, an epigenetic change is defined as a heritable change in gene expression that does not involve a change in the DNA sequence. Epigenetic mechanisms play an essential role in eukaryotic gene regulation by modifying chromatin structure, which in turn modulates gene expression. Convincing evidence indicates that epigenetic mechanisms, and in particular impaired T cell DNA methylation, provide additional factors contributing to the pathogenesis of SSc (Jungel et al, 2010).

In addition to providing a permissive environment for the development of SSc, genetic factors may also be involved in the phenotypic expression of the disease (Derk et al, 2003).

-Causative agents: Environmental and infectious agents

According to the theory of “molecular mimicry” autoantibodies (antibodies against self-antigens) are produced because the self-antigens contain epitopes that share structural similarities with viral or bacterial proteins. In SSc, it has been hypothesized infectious agents (herpes viruses, retroviruses and human cytomegalovirus) as possible causative/co-causative agents. This hypothesis is supported by: 1) the observation of a higher prevalence of IgA antihuman cytomegalovirus antibodies in patients with SSc (Lunardi et al, 2006 ; Neidhart et al, 1999); 2) the demonstration of sequence homologies between retroviral proteins and topoisomerase I antigen which is the target of Scl-70 (Jimenez et al, 1995); 3) the observation that the induced expression of retroviral proteins in normal human dermal fibroblasts results in the acquisition of a SSc-like phenotype in the production of extracellular matrix proteins (Jimenez et al, 1995). Despite these findings more consistent evidence for the involvement of the infectious agents in the aetiology or pathogenesis of SSc is still needed.

III.2 Microchimerism

Microchimerism has been defined by the presence of a low number of circulating cells transferred from one individual to another, during pregnancy, blood transfusion, blood-marrow and solid-organs transplants. An increased presence of microchimeric cells has been observed in peripheral blood and tissues of patients with SSc (Artlett et al, 1998 ; Artlett et al, 2003 ; Nelson et al, 2001).

III. 3 Vascular damage

Vascular dysfunction is one of the earliest alterations considered to be one of the initiating steps in SSc pathogenesis (Matucci-Cerinic et al, 2013). Endothelial injury, preceded by endothelial activation, involves mainly microcirculation and is mediated by cytokines produced by activated lymphocytes (Jungel et al, 2010)

and by antibodies against endothelial cells (AECA) (Renaudineau et al, 1999). Activated lymphocytes secrete cytokines and chemokines, that will lead to endothelial cell injury and expression of MHC and intercellular adhesion molecule-1 (ICAM-1) favouring inflammatory recruitment. Thereafter, growth factors such as TGF beta and connective tissue growth factor CTGF are produced increasing the production of the extracellular matrix, and upregulate platelet derived growth factor (PDGF). Increased PDGF expression promotes endothelial cell proliferation and downregulates vascular endothelial growth factor (VEGF), which usually promotes neovascularisation (Kahaleh, 1994).

Events that follow endothelial activation and endothelial damage are:

- The loss of normal vasomotor tone regulation with a decrease of vasodilators as nitric oxide, and increase of vasoconstrictors as endothelin I (Gruschwitz et al, 1995).
- The chemo-attraction and adhesion of inflammatory cells (Kuryliszyn-Moskal et al, 2005 ; Cutolo et al, 2000).
- The exposure of sub-endothelium to the blood stream: this may induce circulating platelets, to adhere to it and initiate fibrin deposition and intravascular thrombus formation.
- Activation of vascular muscle cells and their migration into the intimal layer of the blood vessel where they differentiate into myofibroblasts.

These alterations lead to the enhancement of vascular damage, with proliferation of vascular intima, narrowing of the vessel lumen with reduction of blood flow, and subsequent clinical manifestations such as digital ischemia and ulcers.

A later stage of the disease is characterised by vessel loss (Cutolo et al, 2000). In SSc, this seems to be due to an abortive neoangiogenesis. The levels of circulating endothelial progenitor cells (EPCs) that differentiate into endothelial cells were found significantly higher in SSc patients than healthy controls (Avouac et al, 2008). However, low EPC levels were associated with higher disease severity and the presence of digital ulcers, suggesting their recruitment in ischaemic tissues and sites of injury during active vascular lesion or severe disease (Avouac et al, 2008). In addition, EPCs from early SSc gave rise to some degree of in vitro endothelial differentiation and their circulating levels were significantly higher than in patients with a late disease suggesting that an altered differentiation may be a later step of the disease pathogenesis (Del Papa et al, 2006). Furthermore, EPCs functions seem to be impaired in SSc (Kuwana et al, 2014) and this might relate to the role of pentraxin 3 (Shirai et al, 2015).

Besides this, a failure of endothelial repair following SSc-related damage seems also to be linked to an alteration in endothelial differentiation of mesenchymal stem cells. These are multipotent cells present in

adult bone marrow and display some features of mature endothelial cells, such as the expression of vWf, VEGFR1, VEGFR2, VE-cadherin and VCAM1. In mesenchymal stem cells of SSc patients a decreased percentage of VEGFR2+, CXCR4+, VEGFR2+/CXCR4+ cells has been found; indeed, the angiogenic potential of endothelial like mesenchymal stem cells was reduced after being stimulated with VEGF and SDF-1, suggesting that endothelial repair may be affected in SSc starting from the bone marrow (Cipriani et al, 2007).

Oxidative stress has been also suggested to play a role in SSc pathogenesis. Ischemia/reperfusion injury following Raynaud's phenomenon can generate reactive oxygen species (ROS) that may result in vascular endothelial damages (Butler et al, 1995 ; Herrick et al, 1994). Furthermore, 8-isoprostane, which is a reliable oxidative stress marker, increases in urine, bronchoalveolar lavage, and serum samples in patients with SSc. Elevated urine levels of 8-hydroxy-2'-deoxyguanosine (8-oxodG) has been found in SSc patients, especially in those with a fibrotic phenotype, supporting high DNA oxidative damage in SSc (Avouac et al, 2010).

Increased levels of serum heat shock protein (Hsp) 70, which is a biomarker of cellular stress, are observed in SSc patients and correlate with disease severity, especially fibrosis and vascular damage (Ogawa et al, 2008). A recent paper has highlighted a potential role of antibodies to methionine sulfoxide reductase A (MSRA), one of the antioxidant repair enzymes, in SSc pathogenesis. In fact serum anti-MSRA levels were significantly elevated in SSc patients with pulmonary fibrosis, cardiac involvement and renal vascular damage and correlate positively with serum levels heat shock protein 70 that are markers of oxidative and cellular stresses. Besides this, MSRA activity was inhibited by IgG isolated from SSc sera containing IgG anti-MSRA antibody, indicating that these antibodies may enhance the oxidative stress by inhibiting MSRA enzymatic activity (Ogawa et al, 2010).

Interestingly, a growing body of evidence suggests that endothelial cell plasticity may play a critical role in various developmental and pathological processes, and, recently, it has been proposed a possible pathogenic role of endothelial mesenchymal transition (EndMT) in SSc (Cipriani et al, 2016). During EndMT, resident endothelial cells may delaminate from the polarized cell layer, invade the underlying tissue and acquire myofibroblast features, thus, contributing to fibrosis production. Specifically, EndoMT is a phenotypical conversion in which endothelial cells downregulate the expression of their specific markers and acquire mesenchymal cell products such as α -SMA, S100A4/fibroblast-specific protein-1 and type I collagen, together with the nuclear translocation of the transcriptional regulator Snail1, a trigger of mesenchymal transition (Manetti et al, 2017). EndoMT may contribute to the pathogenesis of tissue fibrosis and fibroproliferative vasculopathy such as cardiac fibrosis and primary pulmonary arterial hypertension (PAH) and multiple pathways implicated in SSc pathogenesis, such as transforming growth factor- β (TGF β), endothelin-1 (ET-1), oxidative stress and hypoxia, may activate and participate in the molecular mechanisms of the EndoMT process (Mendza et al, 2016; Good et al, 2015). In fact, it has been shown that EndoMT may be induced by TGF β and ET-1 in cultured endothelial cells from SSc patients and healthy controls (Cipriani et al, 2015a).

Therefore, taking together these data it has been proposed that during SSc, profibrotic myofibroblasts may also derive from activation of resident endothelial cells and perivascular pericytes. Interestingly, macitentan, a novel specific endothelin receptor antagonist may interfere with EndMT process in vitro, thus suggesting a new potential therapeutic target in SSc patients (Cipriani et al, 2015b).

III. 4 Immune activation\Inflammation

Innate, humoral and cellular immune system alterations and persistent tissue inflammation play an important pathogenetic role in SSc.

Recent data have highlighted a potential contribution of innate immunity in the pathogenesis of SSc. The strong association of IRF5 variants with SSc as in many other CTDs is an important clue and in addition recent data have showed that Toll-like receptor (TLR) agonists may be important stimuli of dermal fibrosis, which is potentially mediated by TLR3 or other innate immune receptors (Farina et al, 2010).

The activation of humoral immunity is demonstrated by the numerous autoantibodies that have been described in SSc. The presence of antinuclear antibodies can be found in more than 90% of patients with SSc. Anti-Scl-70 antibodies react with nuclear enzyme DNA topoisomerase I and are almost exclusively found in patient with dcSSc, but only 30-40% of these patients present anti-Scl 70. Anticentromere antibodies are present in 80-90% of patients with lcSSc and recognize several protein components of the three-laminar kinetochore. Anti-Scl 70 and anticentromere antibodies rarely coexist in the same patient. Other autoantibodies are less common in SSc, as anti-RNA polymerases II and III antibodies, found in patients with rapidly progressive disease and severe internal organ involvement. Studying cancers occurring in SSc patients, genetic alterations of the POLR3A locus were identified in patients with positive RNAPolIII antibodies (Joseph et al, 2014). Analyses of peripheral blood lymphocytes and serum showed that POLR3A mutations triggered cellular immunity and cross-reactive humoral immune responses. These results offer insight into the pathogenesis of SSc with “off-targets” effects of autoantibodies. It raises that cancer should be extensively screened in RNAPolIII positive SSc patients. Finally, it provides support for the idea that acquired immunity helps to control naturally occurring cancers. Interestingly, in the EUSTAR registry, anti-RNAPIII were associated in multivariable analysis with malignancies concomitant to SSc onset (Lazzaroni et al, 2017).

Antifibrillarin antibodies may be found in dcSSc and anti-PM-Scl antibodies found in SSc patients without inflammatory myopathy. Although autoantibodies are very common in SSc, it is not yet demonstrated that they are directly involved in the disease pathogenesis.

Antifibrillarin antibodies may be found in dcSSc and anti-PM-Scl antibodies found in SSc patients without inflammatory myopathy. Although autoantibodies are very common in SSc, it is not yet demonstrated that they are directly involved in the disease pathogenesis.

Autoantibodies against angiotensin II type I receptor (AT1R) and endothelin-1 type A receptor (ETAR) may play important roles in the pathogenesis of SSc. These autoantibodies regulate physiological processes ranging from production of collagen by skin fibroblasts to angiogenesis modulation (Cabral-Marques et al, 2016). In a previous study, serum samples from 478 patients with SSc, 372 healthy subjects and 311 control-disease subjects were analysed for AT1R and ETAR. These autoantibodies were detected in most patients with SSc. These autoantibodies specifically bound to respective receptors on endothelial cells. Higher levels of both autoantibodies were associated with more severe disease manifestations and predicted SSc-related mortality, suggesting possible biomarkers. Furthermore, both autoantibodies showed biological effects inducing extracellular signal-regulated kinase 1/2 phosphorylation and increased transforming growth factor β gene expression in endothelial cells which could be blocked with specific receptor antagonists (Riemekasten et al, 2011).

The cellular immune system and the consequent chronic inflammation has an important role as mononuclear cell infiltrates are found in affected skin and visceral organs of SSc patients. The mononuclear cells within the skin infiltrates are predominantly CD4+T cells and express the activation marker class II MHC antigen DR (Kraling et al, 1995 ; Chizzolini, 2015). Subsequent oligoclonal expansion of these cells within the tissues has been observed (Sakkas et al, 2002), suggesting an antigen-driven response, although there is no information on the putative antigen or antigens that may be involved.

Recently also CD4+CD25+ regulatory T cells has been investigated in SSc pathogenesis; these cells are able to suppress proliferation of effector T cells playing a crucial role in determining the self-tolerance. In SSc sera CD4+CD25+ were markedly increased but showed an aberrant expression of phenotypic markers that is associated with a reduced suppressive function (Radstake et al, 2009 ; Klein et al, 2011).

The role of T cells in the development of dermal fibrosis has been recently suggested by the invalidation of STAT4 in the mouse model of bleomycin induced dermal fibrosis, mimicking early inflammatory stages of SSc. STAT4 is a transcription factor that promotes inflammation during protective immune responses and immune-mediated diseases. STAT4 deficient mice were protected from the development of dermal fibrosis, in this mouse model. In addition, STAT4 also regulated fibroblast activation and collagen release indirectly, by orchestrating T cell infiltration and regulating proinflammatory cytokine production (Avouac et al, 2011). These findings support the contribution of STAT4 and T cells in the development of inflammation driven fibrosis, hallmark of early stages of SSc, characterized by the infiltration of inflammatory cells in lesional tissue.

IL-17 is a proinflammatory cytokine with non-redundant functions in the clearance of extracellular pathogens. An increase in frequency of Th17+ cells has been reported in several autoimmune diseases. Some recent reports suggest an increased frequency of Th17 cells in peripheral blood of patients with SSc together with a decrease in frequency or suppressive activity of Tregs in these patients although some discrepancies have

been found regarding peripheral blood versus dermal tissue (Brembilla et al, 2012). Larger studies and functional data are now required to confirm the potential role of Th17 and Tregs in SSc. A large candidate gene study further highlighted the potential implication of Th17 pathway in SSc, by establishing CCR6 (a surface marker for Th17 cells) as a new susceptibility factor for anti-topoisomerase-positive SSc and showing a robust association of a regulatory variant (Koumakis et al, 2013).

In SSc the B cell hyperactivity and hyper-g-globulinaemia suggests the presence of an abnormal B cell activation (Fujimoto et al, 2005); then the presence of B cell infiltration has been detected in the skin and the lung of SSc patients (Lafyatis et al, 2007). In particular, CD22, a B cell-specific inhibitory receptor, has a disrupted cell signalling in SSc, leading to abnormal B cell activation and autoantibody production (Fujimoto et al, 2007). A recent study has demonstrated the presence of circulating autoantibodies to CD22 in SSc patients and these antibodies were capable of reducing phosphorylation of all CD22 tyrosine motifs, interfering with the suppression on B cell activation (Odaka et al, 2010).

Chemokines could be of major importance in SSc. Previous reports have highlighted the potential implication of MCP-1 by example but a recent study raised the potential important role of CXCL4. Using an unbiased proteomic approach and plasmacytoid cells, the authors identified CXCL4 as overexpressed by cells issued from SSc patients (Van Bon et al, 2014). They then were able to correlate CXCL4 levels with skin and lung fibrosis and with pulmonary arterial hypertension. CXCL4 is a protein that was first identified as a product of megakaryocytes and is well accepted as one of the most potent antiangiogenic chemokines. In addition, CXCL4 inhibits the expression of the antifibrotic cytokine interferon- γ and up-regulates profibrotic cytokines interleukin-4 and interleukin-13, and also stimulates the proliferation of T regulatory cells with impaired suppressive function. The exact source of CXCL4 remains to be determined such as platelets were found to be critical to mediate experimental liver fibrosis but CXCL4 appears as an attractive candidate to link vascular, immune and fibrotic features related to SSc and potentially others fibrotic diseases.

III. 5 Fibrosis

Fibrosis is the final step of SSc pathogenesis and is responsible of the most prominent clinical manifestations of disease. It is due to an increased fibroblast production of collagen, especially types 1 and 3, with type 1 being the most abundant. It is not known if the excessive production of connective tissue represent an altered response to an unknown injury or if is due to the primary alteration in the regulation of expression of matrix protein genes. The persistent activation of collagen genes differentiates the uncontrolled fibrosis of SSc from normal response to injury. The persistent activation of collagen genes differentiates the uncontrolled fibrosis of SSc from normal response to injury. In this context, it has been suggested that, after vascular and immunological damage, the development of fibrosis, in different organ, may be related to several pathogenic mechanisms, including expansion and activation of resident tissue fibroblasts, endothelial cells and perivascular pericytes,

recruitment of bone marrow-derived circulating precursors, transformation of white adipocytes and transdifferentiation of epithelial cells as well as endothelial cells into mesenchymal cells, resulting in hyperactivation of fibroblasts and myofibroblasts (Zeisberg et al, 2010; von Gise et al, 2012). A number of cytokines and growth factors released from the tissue inflammatory cells can stimulate collagen gene expression (White, 1996 ; Postlethwaite 1995).

Transforming growth factor beta (TGF β), produced by activated lymphocytes and monocytes, plays a crucial role in SSc related fibrosis as it stimulates the extracellular matrix synthesis (Varga et al, 1987), but also decreases the production of collagen degrading metalloproteinases and stimulates the production of protease inhibitors (as tissue inhibitor of metalloproteinases-1), which prevent break-down of the extracellular matrix (Gerber et al, 2013). The production of TGF β is consistently upregulated in SSc, maintaining fibroblasts from SSc patients in an activated state. SSc fibroblasts on the other hand express increased number of TGF β receptors, enhancing collagen production. The main alterations of TGF β signalling that play an essential role in the persistent activation of SSc fibroblasts are represented by an up-regulation of α v β 5 and α v β 3 integrins, which contribute to activation of latent TGF β and establishment of the autocrine TGF β loop. Additional changes include alterations of the TGF β receptor ratio and the presence of persistently phosphorylated Smad3. Nuclear receptors are good candidate to play a primary role in fibrosis. NR4A1 recruits a repressor complex and acts as an endogenous inhibitor of TGF- β . Even though temporary upregulation of TGF- β in physiologic wound healing induces NR4A1 expression and thereby creates a negative feedback loop. The persistent activation of TGF- β signalling in fibrotic diseases uses AKT- and HDAC-dependent mechanisms to inhibit NR4A1 expression and activation. NR4A1 small-molecule agonists showed their ability to overcome this lack of active NR4A1 and inhibit experimentally-induced skin, lung, liver, and kidney fibrosis in mice, providing a proof of concept for targeting NR4A1 in fibrotic diseases (Palumbo-Zerr et al, 2015). Several lines of evidence suggest that peroxisome proliferator-activated receptors (PPARs) could play an important role in SSc-related fibrosis. Low levels of both PPAR α and PPAR γ were detected in the skin of patients with SSc compared with controls. The use of IVA337, a pan-PPAR agonist, in mice was associated with decreased extracellular matrix deposition and reduced expression of phosphorylated SMAD2/3-intracellular effector of TGF- β 1. Furthermore, a dampening effect on both inflammation and fibrosis was observed in mice challenged by bleomycin. Simultaneous activation of all three PPAR isoforms exerts an anti-fibrotic action, making IVA337 a potentially therapeutic candidate in fibrotic diseases including SSc (Ruzehaji et al, 2016).

Fibrillin-1 is a modular glycoprotein encoded by the large (230-kb) FBN1 gene located in 15q21.1 region. This region has been mapped in Choctaw Indians as potentially harbouring SSc associated genes and the animal model TSK-1, which recapitulates some of SSc changes, relates to a Fibrillin-1 gene duplication. Fibrillin is a major constituent of microfibrils in the extracellular matrix and is highly homologous to latent TGF-beta binding proteins. These proteins bind to the small latent TGF-beta complex and sequester it to the extracellular matrix.

Mutations of the FBN1 gene cause Marfan syndrome and also stiff skin syndrome that is characterized by hard, thick skin, usually over the entire body, which limits joint mobility and causes flexion contractures. Failed matrix sequestration of the latent complex in fibrillin-1-deficient patients and mice promotes increased signalling by TGF- β . The stiff skin syndrome mutations are specifically localized to the fourth TGF- β -binding protein-like domain, which encodes the RGD motif, through which fibrillin-1 binds several integrins. Two Fbn1-targeted knock-in mouse models were recently generated to demonstrate that impaired interaction between integrins and fibrillin-1 initiates skin fibrosis (Leask et al, 2002). Moreover, mutant mice exhibit skin infiltration of pro-inflammatory immune cells and also autoantibody production and of the most interest, these findings could be normalized by integrin-modulating therapies or TGF- β blockers (Gerber et al, 2013). Altogether, these data highlight that cell–matrix interactions are critical in the relationships between inflammation/immunity and fibrosis and might represent promising new therapeutic avenues.

Connective tissue growth factor (CTGF) is another potentially important mediator of tissue fibrosis (Ihn, 2002). It stimulates the synthesis of extracellular matrix components in dermal and lung fibroblasts: it is produced by fibroblasts, vascular smooth muscle cells and endothelial cells in response to TGF β stimulation and in autocrine fashion CTGF can stimulate its own production (Svegliati et al, 2005). It has been hypothesized that CTGF might act as a downstream mediator of TGF β effects, that once activated, could chronically perpetuate collagen overproduction in SSc.

Besides this, oxidative stress in SSc affects fibroblasts, which show the accumulation of large amounts of reactive oxygen species (ROS); these are key cell transducers of fibroblast proliferation and collagen-gene expression. A pathway linking the signalling proteins Ha-Ras, growth-factor–activated extracellular-signal–regulated kinases 1 and 2 (ERK1/2), and ROS is amplified in fibroblasts from patients with scleroderma (Baroni et al, 2006).

IV Clinical manifestations

The disease is commonly called "scleroderma" because the most visible aspect is "hard skin", however, scleroderma is a systemic disease and besides the significant aesthetic changes of the face (figure 5) and extremities, organ involvement leads to a functional reduction, sometimes progressing to organ or multiorgan end-stage failure. The disease has various clinical characteristics because it involves the skin as well as the internal organs. At onset, some patients present with few changes, making the diagnosis sometimes difficult to establish even for scleroderma experts. Below is an in-depth description of the various types of internal organ involvement observed in SSc.

Table 5: Prevalence of clinical features in EUSTAR cohort by disease subtype

n/total (%) or mean \pm SD EUSTAR ^a # n=13996	Limited (n=7273)	Diffuse (n=4034)
Female	6525 (89.8%)	3152 (78.2%)
Age at recruitment, mean \pm SD (range), years	57.00 \pm 13.67	51.58 \pm 13.81
Disease duration at recruitment*, years	9.10 \pm 8.62	6.79 \pm 7.22
Anti-centromere pattern ANA	3487 (50.8%)	282 (7.7%)
Anti-Scl 70 +ve	1534 (22.6%)	2226 (58.9%)
Anti-RNAP +ve	64 (2.6%)	109 (9.0%)
Raynaud's phenomenon	6929 (96.4%)	3855 (96.1%)
Rodnan skin score (highest ever)	6.78 \pm 5.42	17.64 \pm 10.24
Digital ulcers ever	1936 (27.1%)	1530 (38.4%)
Digital gangrene/ amputation	42 (3.5%)	29 (4.2%)
Joint contractures	1454 (20.3%)	1849 (46.5%)
Tendon friction rubs	338 (4.8%)	683 (17.3%)
Synovitis	896 (12.5%)	785 (19.7%)
ILD (HRCT scan)	1663 (27.0%)	1675 (48.6%)
Pericardial effusion	174 (2.4%)	141 (3.5%)
Renal crisis ever	82 (1.1%)	161 (4.0%)
Malabsorption	33 (3.2%)	31 (5.0%)
Home oxygen ever	75 (2.1%)	51 (2.5%)

*Disease duration from first non-Raynaud disease manifestation. Disease manifestations defined as present if ever present from SSc diagnosis. Data are presented as number and percentage of those with data available.

^a15-40% missing data; [#]41-75% missing data; ^bmore than 75% missing data. EUSTAR database, unpublished data.

Figure 5 - Face in acute diffuse SSc

IV.1 Vascular manifestations

The earliest symptom of SSc is Raynaud's phenomenon (RP) of the fingers, toes, ears, and nose: it is characterized by episodic vasospastic attacks that cause the blood vessels in the fingers and toes to constrict. RP presents with three changes in skin colour (Neidhart et al, 1999). Pallor (in response to spasm of the arterioles and the resulting collapse of digital arteries) followed by cyanosis (due to ischemia) and finally, as the reperfusion dilation, rubor occurs. The duration of an attack varies from less than one minute to several hours. As the attack ends, throbbing and tingling may occur in the fingers and toes. Connective tissue diseases, such as SSc, are the most common cause of secondary RP (LeRoy et al, 1988).

Nailfold video-capillaroscopy (NVC) shows a variety of morphological changes including enlarged capillaries, bushy capillary formations, micro haemorrhages, and a variable loss of capillaries with or without avascular areas. Capillaroscopic patterns in SSc may vary according to the disease stage and Early (new enlarged/giant capillaries, few capillary haemorrhages, relatively well-preserved capillary distribution, no evident loss of capillaries), Active (frequent giant capillaries, frequent capillary haemorrhages, moderate loss of capillaries, mild disorganization of the capillary architecture, absent or mild ramified capillaries) and late (irregular enlargement of the capillaries, few or absent giant capillaries and haemorrhages, severe loss of capillaries with extensive avascular areas, disorganization of the normal capillary array, ramified/bushy capillaries) stages have been identified (figure 6) (Cutolo et al, 2003). Some studies have described the morphological aspects of vascular damage in patients with SSc by NVC, correlating these capillary abnormalities to selected

characteristics of the disease. Further scoring systems are also under investigations in an attempt to evaluate capillaroscopy not only as a diagnostic tool but potentially as an activity or severity marker.

Figure 6: Normal and systemic sclerosis nailfold capillaroscopy patterns

The prospective follow-up of 586 consecutive patients referred for evaluation of RP who had no definite connective tissue disease at baseline revealed that 74 (12.6%) developed definite SSc. Scleroderma capillaroscopic pattern and SSc specific auto-antibodies were both predictors of SSc and had additive effects (the higher risk, close to 60 fold, was observed for patients with both abnormal capillaroscopy and positive SSc autoantibodies at baseline) (Koenig et al, 2008).

Fingertips ulcers may arise as a complication of RP and chronic ischemia and occur in patients both with limited or diffuse systemic sclerosis (SSc). Usually ulcers heal slowly and become portals for infections that may evolve to gangrene and, as they deepen into the tissues, bone involvement can occur, which may result in osteomyelitis. In the worst refractory cases, digital amputation may be needed (Bogoch et al, 2005). In SSc, digital tip ulceration occurs in about 31.8–71.4% (median 45.2%). Digital ulcerations are usually slow healing and 14–29% progress to gangrene and auto amputation (Nihtyanova et al, 2008). The frequency of severe

digital vasculopathy related complications emerged in a recent study (Amanzi et al, 2010) is reported in figure 7.

Figure 7: Complications of ulcers in a SSc cohort of patients (from Nihtyanova ARD 2008)

In the early phase of SSc, ulcers are localised on fingertips (figure 8A), malleoli, heel, and great toe. With disease progression, ulcers may be found over bony prominences (figure 8B), and may be provoked mainly by mechanical retraction of the skin, especially to the dorsal aspect of the interphalangeal joints and elbows. Usually, these parts are exposed to repetitive trauma at sites of chronic contractures. The avascular, atrophic nature of the tissue overlying these sites results in vulnerability to injury and impaired healing.

Figure 8A and 8B: Localisation of digital ulcers in early diffuse SSc (A) and gangrene with amputation in late diffuse SSc (B)

In SSc, a clinical evidence-based classification of DU is still lacking and today the increase in studies on DU highlights the need for a clear-cut classification of DU. This has become a major necessity to make both studies and outcomes uniform, as in previous randomized controlled trials and open studies, different definitions have been proposed.

A recent study has classified fingertip ulcers as follows (Amanzi et al, 2010):

1. Derived from Digital pitting scar: these ulcers are hyperkeratotic and thick small (2-3 mm) scars are localised on the fingers. They are a white or yellow, undermined and continuously painful (figure 8).
2. Characterized by Loss of tissue: ulcers are characterised by loss of tissue, at different levels and at different sites that may deepen down to the bone (figures 9). They are frequently undermined and painful. When they occur over bony prominences they are due to tissue retraction, as showed in figure 7.
3. Derived by Calcinosis: it is defined as deposits of calcium phosphate in soft tissues, visible to the naked eye and/or confirmed by X-ray They may occur anywhere, with variable dimension and are hard, adherent to the bottom of the ulcer or tissues, painful and are frequently complicated by infection, with or without fistulisation (figure 10)

Ulcers may evolve in gangrene that is defined as the death of tissues caused by a total lack of blood supply. Macroscopically, the affected part is dry, shrunken and dark black. On the dorsal aspect of the fingers in particular on PIJ skin retraction may provoke cutaneous breaks forming ulcers.

Figure 9: Yellow (9A) and white (9B) pitting scar

Figure 10: Ulcers developed on calcinosis of the knee in a patient with SSc. In the box calcium depositions that have been removed are shown.

-according to the depth:

1. Superficial: partial thickness skin loss involving epidermis. The ulcer is superficial and presents clinically as an abrasion, blister or tiny crater.
2. Intermediate: full thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.
3. Deep: full thickness skin loss with extensive destruction, or damage to muscle down over the fascia, supporting structures (e.g. tendon, joint capsule) and bone)

The main features that should be evaluated when dealing with SSc ulcers are:

- localization (fingertips, nail area, dorsal and palmar aspect of the finger);
- dimensions (area in square millimetres);
- bed of the lesion (re-epithelialization, granulation tissue, fibrin, wet or dry necrosis, eschar and gangrene);
- exudate (low, high, pus);
- borders of the lesions (regular or irregular);
- perilesional skin (normal or inflamed) and oedema;
- bone and tendon exposure and auto amputation;
- pain

Using the Eustar registry, the prevalence and outcomes of SSc-DU patients have been described. Out of 3196 patients with longitudinal data (malegender 13%, 33% diffuse subset), 1092/3196 patients had a history of DU at baseline. In multivariable analysis adjusting for age, gender and all parameters considered potentially

significant, a history of DU was predictive for the presence of active DUs at prospective visits (HR (95% CI)): 2.41 (1.91 to 3.03), $p < 0.001$, for an elevated systolic pulmonary arterial pressure on heart ultrasound :1.36 (1.03 to 1.80), $p = 0.032$, for any cardiovascular event (new DUs, elevated US-PAPs or heart failure): 3.56 (2.26 to 5.62), $p < 0.001$, and for death (1.53 (1.16 to 2.02), $p = 0.003$). As expected a history of DU is the strongest predictor of new DU but also seems to predict overall worse cardiovascular outcomes (Mihai et al, 2015).

IV .2 Gastrointestinal Tract Involvement

Fibrosis can involve the entire gastrointestinal (GI) tract, making the muscle wall of these organs atrophic. Damage to the gut's nervous system may cause dysmotility, it is thought to be an early event and might be promoted by the vasculopathy. Oesophageal dysmotility is very common and its problems occur in 75-90% of SSc patients, stomach involvement in at least 50%, small bowel involvement in 40-70%, colon involvement in 20-50%, and anorectal involvement in 50-70% (Sjögren, 1994).

IV.2.1 Upper Tract: Oesophageal disease is characterized by poor functioning of the muscle of the lower part of the oesophagus (Cohen et al, 1972). This causes a reduction of the peristalsis and of the continence of the lower oesophageal sphincter (LES) that manifests as dysphagia and reflux episodes that are responsible of oesophagitis of lower part of oesophagus, causing heartburn, pyrosis, and regurgitation. Other less common symptoms are sore throat, laryngitis, inflammation of the gums, erosion of tooth enamel, chronic irritation in the throat, and hoarseness in the morning. Sometimes there are no symptoms, and the presence of gastro oesophageal reflux is revealed through other complications (Zamost et al, 1987). Oesophageal motility is usually tested by manometry. This test evaluates the amplitude, the duration, the velocity and the presence or absence of peristaltic contractions and determines whether the measurements are within normal range (Klein HA et al, 1992). In a recent series of about 60 patients fulfilling the VEDOSS criteria, it has been shown that the lower oesophageal sphincter pressure and peristalsis were significantly abnormal (peristalsis was absent in 25.5% of the patients), and oesophageal symptoms were detected in 49%. This confirms that upper GI is an early event in the disease course (Lepri et al, 2014).

In a small subset of patients, Barrett's oesophagus can develop as a complication of oesophagitis. This is a potentially precancerous condition in which the mucosa of the oesophagus is transformed into a "specialized intestinal metaplasia" (figure 11A). To evaluate tissue damage, upper endoscopy is recommended. If Barrett's oesophagus is detected, routine endoscopic screening is advised usually every 3 years in the case of lack of dysplasia, every year if low grade dysplasia is found and every 3 months in the case of high grade dysplasia with discussion of local therapy if in situ cancer occurs (Wipff et al, 2005 ; Wipff et al, 2011).

For people with symptoms of gastro oesophageal reflux, a pH-monitoring test can be performed (Leite et al, 1997). The abnormality of the gut's nervous system present in SSc also can involve the stomach's electrical

rhythm, with the motility becoming weakened, spastic, or failing completely. In the most severe forms, nausea, vomiting, abdominal pain, and severe constipation are unrelenting.

Gastroparesis, or small bowel dysmotility, is at the extreme end of the symptom spectrum. The range of symptoms includes nausea, vomiting, belching, reflux, sensation, early satiety, abdominal pain, abdominal bloating, change in bowel habits, and weight loss (Wegener et al, 1994). Gastric emptying time (GET) is the diagnostic test used for gastroparesis.

Watermelon stomach (WS) or Gastric Antral Vascular Ectasia (GAVE) is a very rare gastric complication of SSc. It has a unique endoscopic appearance that is characterized by multiple longitudinal stripes of red vessels, which are limited to the gastric antrum and which radiate in a spoke-like fashion from the pylorus to the antrum (figure 11B). WS seems to be a component of the general microangiopathy that characterizes the disease. However, despite the large use of gastroscopy, prevalence of SSc-WS remains unclear with only one monocentric, retrospective study, which reported 5.7% of WS among 264 SSc patients with anaemia (Ingraham et al, 2010). However, in a recent large Eustar survey, the prevalence of GAVE was estimated at about 1% of patients with SSc (49 cases identified) (Ghrénassia et al, 2014). In this controlled study, GAVE was associated with the presence of anti-RNA-polymerase III antibodies (OR 4.6; 95% CI 1.2-21.1). In a clinical perspective, SSc-GAVE was mainly associated with anaemia (82%) requiring blood transfusion (45%). Therapeutic endoscopic procedures were performed in 45% of patients with GAVE. After a median follow-up of 30 months (range 1-113 months), survival was similar in patients with SSc-GAVE compared to controls, but a higher number of scleroderma renal crisis cases occurred (12% vs 2%; $p = 0.01$).

These results support previous findings with early occurrence predominating in diffuse cutaneous SSc versus late onset (over 15 years) in limited cutaneous, such as a probable link with anti RNA polymerase III antibodies. The more common clinical manifestation is anaemia, which could be present in 95 to 100% of cases with 90% of chronic occult bleeding and 10% of acute haemorrhage. Various therapies have been reported for the treatment of WS, including blood transfusion, oestrogen-progesterone treatment, iron supplementation, steroids, and surgery. Laser YAG can be a useful treatment with 85% of success at the short-term, like argon plasma electrocoagulation (Shibukawa et al, 2007).

Figure 11: Histological and macroscopic picture of some upper GI complications

11A: BE was defined by the finding of intestinal architecture in the lower oesophagus displaying a villiform columnar-lined mucosa with goblet cells; these features of BE were identified by classic coloration on haematoxylin and eosin staining. 11B: Endoscopic aspect of watermelon stomach

IV.2.2 Lower Tract

The small bowel can become dilated and often atonic, losing its propulsive function. Under these conditions bacteria that normally live in the small bowel grow enormously, damaging the mucosa that absorbs food. This leads to malabsorption, with significant loss of absorption of essential nutrients. Bacterial overgrowth syndrome or Small Intestinal Bacterial Overgrowth (SIBO) occurs when the normally low colonization of bacteria in the upper GI tract increases significantly (Greydanus et al, 1989). Fat, protein, carbohydrate and vitamin malabsorption result from poor enterocyte function and from bacterial transformation of nutrients into nonabsorbable and toxic metabolites, all of which contribute to damage of the intestinal mucosa.

Breath tests using by-products of bacterial metabolism to identify malabsorbed substances are useful in determining the diagnosis. The most sensitive and specific is the xylose breath test, which is based on the fact that overgrowth of Gram-negative bacteria in the small bowel, which occurs during dysmotility disorders, leads to metabolism of xylose and results in the release of radioactive carbon dioxide. In the most severe cases, bowel dilatation may result in a condition known as intestinal pseudo-obstruction (figure 12). Clinical expression is characterised by nausea, diarrhoea, abdominal distension, weight loss and commonly intermittent abdominal crisis with frank distension and postprandial bloating. Such cases, patients should avoid oral feeding and will require the use of continuous nasogastric suction. When malnutrition is evident, total parenteral nutrition is indicated.

Because gastrointestinal tract (GIT) involvement occurs in approximately 90% of patients with SSc and also because it has a negative impact on health-related quality of life, it is important to carefully assess this part of

the disease, and include it in future trials. Following the Food and Drug Administration draft guidance on the development of a patient-reported outcome measure, the UCLA Scleroderma Clinical Trial Consortium GIT 2.0 has been built and its reliability and validity recently demonstrated (Khanna et al, 2009). Sensitivity to change is now under examination but this tool should improve the management of SSc patients (it is available through EUSTAR website).

A summary of the various GI involvements, mechanisms and tools of assessment is presented in Table 5.

Figure 12: lower GI involvement: abdominal CT scan showing that the small intestine is filled and distended with air and fluid, with air-fluid levels, evocative of pseudo-obstruction

Table 6: summary of the GI symptoms, mechanisms and tools for assessment

GI	Symptoms	Mechanisms	Assessment
Esophagus	Reflux Heartburn Dysphagia Bleeding	Dysmotility Esophagitis Ulcers	Manometry Endoscopy 24h Ph-metry
Stomach	Satiety, bloating Nausea Vomiting Bleeding	Gastroparesis Telegiectasia	Manometry Scintigraphy Baryum Endoscopy
Intestine	Constipation Diarrhea Abdominal bloating and pain Weight loss	Dysmotility Bacterial overgrowth Pneumatosis Malabsorption	Breath test CT scan Ileocolonoscopy Video capsule endoscopy
Ano-rectal	Incomplete stools outlet Fecal incontinence		Manometry

IV.3 Lung involvement

Pulmonary involvement is the leading cause of morbidity and mortality in SSc patients (Steen et al, 1994) as it frequently complicates SSc provoking loss of quality of life and a poor expectation of survival. Alveolitis, membrane thickening and/or the modification of microvascular structure are the main hallmarks of lung involvement that may lead, with the progression of the disease, to ILD and to pulmonary artery hypertension. Non-specific interstitial pneumonia (NSIP) is the most histopathological pattern found in SSc lung, although usual interstitial pneumonia (UIP) can be present (Kim et al, 2002 ; Bouros et al, 2002). NSIP is characterized by varying degrees of inflammation and fibrosis but does not present the heterogeneity of UIP (it lacks fibroblast foci and honeycombing) (Travis et al, 2008). In idiopathic lung fibrosis patients with NSIP have better prognosis than those with UIP. This difference has not been observed in SSc, although overall all forms of lung fibrosis have a better outcome in SSc.

Dyspnoea on exertion, non-productive cough and hypoxemia are the most common manifestations of pulmonary fibrosis. Haemoptysis, airway and lung inflammation can also be observed in advanced fibrosis. Fine bibasilar crackles at chest auscultation are characteristic.

In the early stages there are often no clinical signs to suggest the development of pulmonary arterial hypertension. Increased and palpable pulmonary components of the second heart sound, right ventricular gallops, murmurs of pulmonary and tricuspid insufficiency, jugular distension, hepatojugular distension and feet oedema can reflect signs of pulmonary hypertension.

Chest X-rays can detect lung volumes, the distribution of infiltrates, pleural disease and lymphadenopathy. Chest radiography is not sufficiently sensitive to exclude lung fibrosis in SSc: 10% of symptomatic patients may have a normal chest radiograph as CXR have a low sensitivity for early lung involvement. The pulmonary function test (PFT) in SSc may show a restrictive pattern with decrease of forced vital capacity (FVC) or total lung volume (TLC) –(which is less effort dependent and so can be more reliable than FVC) and diffusion capacity for carbon monoxide (DLCO) (Guttadauria et al, 1977).

Restrictive ventilatory defects are the most common finding (Peters-Golden et al, 1984). However, by the time these defects are diagnosed on spirometry the pulmonary disease is fairly advanced. A reduction in pulmonary carbon monoxide diffusion capacity (DLCO) is reportedly to be an early sign of pulmonary disease in SSc, as well as an important predictor of mortality (Wells et al, 1997). Even so, diffusion across the alveolar capillary units may be altered by parameters other than interstitial fibrosis. The reduction of DLCO alone may also suggest the presence of pulmonary hypertension (Steen, 2003 ; Steen et al, 2000). Assessment of PFT is recommended in SSc since chest radiography or respiratory symptoms cannot predict early lung involvement. However, and despite its value for the functional assessment of the patients, pulmonary PFTs perform poorly to diagnose ILD in SSc patients and cannot be used solely to that end (Suliman et al, 2015).

Chest HRCT is the non-invasive gold standard technique for the diagnosis of SSc ILD (Remy-Jardin et al, 1993). HRCT is recognised as a sensitive tool for predicting the histological characteristics of lung parenchymal abnormalities, in patients with idiopathic pulmonary fibrosis. It allows imaging of the lung parenchyma in remarkable detail that is very useful in the diagnosis of fibrosing alveolitis, providing a non-invasive alternative to open lung biopsy. Ground glass opacification may reflect alveolitis but when there is associated traction bronchiectasis it is more likely due to finer fibrosis. Likewise, inflammatory change cannot be excluded by honeycomb reticular shadowing as there may be sites of inflammation within established disease (Ooi, et al, 2003). A simple staging system with minimal and severe disease on HRCT defined as clearly < 20% or clearly > 20% has demonstrated a high feasibility and a good predictivity value. Indeed, an extensive disease (>20%) on HRCT at baseline is associated with a three-fold increased risk of deterioration or death in SSc-ILD, compared with limited disease (Moore et al, 2013).

Treatment decisions should be based upon clinical evidence of declining lung function in the context of significant HRCT and PFTs changes.

Typical interstitial abnormalities identified on HRCT include thickened interlobular septa, sub pleural cysts, and honeycombing lung formation. Additional findings may include sub pleural micro nodules, small airway ectasia (bronchiectasis and bronchioloectasis) and ground glass opacification (Guttadauria et al, 1977) (figure 13). Ground glass opacification on HRCT correlates to the presence of air space inflammation in the lung (alveolitis) and decreased DLCO. HRCT allows a qualitative assessment (Normal/ground-glass/fibrosis) or semi-quantitative assessment (Wells' or Warrick's scoring systems).

Table 7: summary of the lung involvement, mechanisms and tools for assessment

	Symptoms	Mechanisms	Assessment
Interstitial lung fibrosis	Shortness of breath Exercise limitation	Inflammation Fibrosis	Chest auscultation: crackles PFTs: decline in DL_{CO}, FVC Hypoxemia 6 min walk test HRCT Biomarkers Bronchoalveolar lavage
Pleural disease	Chest pain Shortness of breath	Inflammation	X-Ray HRCT
Lung vessels Pulmonary hypertension	Shortness of breath Exercise limitation Syncope Oedema	Vascular resistance (PAH) <i>versus</i> passive elevation of pulmonary pressure (PH)	Loud pulmonary component (P2) Signs of right sided heart failure Echocardiography HRCT Right heart catheterisation 6 min walk test

Figure 13: HRCT findings in SSc-ILD. A: ground glass opacities evocative of acute alveolitis. B: reticulation and honeycombing evocative of established lung fibrosis

In patients with pulmonary fibrosis, the cell population in the BAL fluid, from different lung sections, is not uniform, and HRCT scanning appears to be a useful method to identify pulmonary areas with different inflammatory activity (Strange et al, 2008). BAL is no more use to measure disease activity and no more included for treatment decision but is still used to rule out infection when required and is a research tool to investigate lung inflammation and lung fibrosis pathogenesis (Schmidt et al, 2009 ; Pignone et al, 1992). Interestingly, a meta-analysis of 27 studies was conducted to identify variables predicting the mortality and ILD progression in SSc patients and, the extent of disease, on HRCT scan, was the only variable that predicts independently, both mortality and ILD progression. Furthermore, DLCO was the most consistent predictor of mortality and may help to identify patients with a poor prognosis; however, more rigorous studies are needed to fully elucidated these data (Winstone et al, 2014).

Clearance of inhaled ^{99m}T-DTPA is an index of lung epithelial permeability (O' Brodovich et al, 1987). Increased ^{99m}T-DTPA clearance may be a sensitive marker of inflammation (Pantin et al, 1988) and normal clearance certifies absence of inflammation (Susskind, 1994). Rapid clearance of ^{99m}T-DTPA can be useful in patients with an isolated reduction in DLCO to differentiate between those with early fibrosing alveolitis and to those with pulmonary vascular disease (Wells et al, 1993).

IV .4 Pulmonary arterial hypertension (PAH)

PAH is a serious and potentially life-threatening condition that can develop in patients with SSc. It occurs when the blood vessels supplying the lungs constrict and then become stiffer and thicker because of irreversible fibrosis. The increased resistance in pulmonary circulation makes it difficult for blood to flow through to the lung vessels, and thus the heart must pump harder leading to heart failure (figure 14) (Denton et al, 2003).

Some patients may have both interstitial lung disease and PAH; the first usually develops early in the disease, whereas PAH tends to occur later, often in the second decade of disease. The prevalence of pre-capillary PAH

has been found to be 9% in a recent meta-analysis that included more than 3800 SSc patients screened for this complication (Yamane, 1994). PAH has been commonly known as a late complication of the disease; however 2 different patient profiles has been suggested by some studies with PAH being a late complication of LcSSc subset but it may occur earlier in the DcSSc subset in particularly as a complication of severe ILD (Avouac et al, 2010).

The precise cause of PAH is unknown, but it is associated with dysregulation of blood flow that results in vasoconstriction, as is observed in Raynaud's phenomenon. Many factors may play a role in this process with imbalance between the synthesis of vasoconstrictor versus vasodilator molecules by injured endothelial cells.

Because of the poor outcome, it is critical to diagnose PAH in an early phase, so that prompt therapy can be initiated while the condition is still reversible. For this reason an early diagnosis is mandatory in order to start an appropriate treatment as soon as possible.

In the earliest stages of PAH, the patient is asymptomatic. Then dyspnoea begins on exertion and later during ordinary activity. Non-specific symptoms such as chest pain, dizziness and fainting may also occur (Ramirez et al, 2004). At physical examination left parasternal lift, an accentuated pulmonary component of second heart sound, a pan systolic murmur of tricuspid regurgitation, a diastolic murmur of pulmonary insufficiency, and an RV third sound may be detected. Lung sounds are usually normal.

The ECG may provide suggestive evidence of PAH by demonstrating right ventricular hypertrophy and strain, and right atrial dilatation; however the absence of these findings does not exclude the presence of PAH (Rich et al, 1987).

Doppler echocardiography should be performed periodically, at least annually, also in asymptomatic SSc patients and is the first line tool to assess PAH. This technique cannot only determine the size of the cardiac chambers of the heart and the state of the valves but may also estimate pulmonary arterial pressure – by using the tricuspid regurgitant jet velocity to estimate right ventricular systolic pressure (Fisher et al, 2009). An estimate of right atrial pressure must be added to estimate PAH. Although there is a strong statistical correlation between estimated systolic PAP and mean PAP this can be misleading. Especially in the important estimated range of 30 to 50 mmHg.

Figure 14: Pulmonary arterial hypertension leading to: - Cardiomegaly with dilation of pulmonary arteries and heart cavities on a plain chest X-Ray (Left). - Dilation of the right atrium and ventricle on echocardiography (Right)

Therefore, once PAH is suspected, whatever the reason, right-heart catheterization must be performed (Galie et al, 2009). The following variables must be recorded during RHC: PAP (systolic, diastolic, and mean), right atrial pressure, PWP, and RV pressure. In PAH, vasoreactivity testing should be performed at the time to identify patients who may benefit from long-term therapy with calcium channel blockers. However, a positive testing is very uncommon in SSc-PAH and, therefore, many teams do not perform this test in SSc patients.

The proportion of post-capillary pulmonary hypertension is increasing within SSc patients. This might come from a better recognition of this situation, but also advanced age and/or more myocardial pathology in SSc patients. It becomes a routine practice to perform both right and left heart catheterization on all patients being evaluated for PH. Furthermore, when the capillary pressure and the left ventricular end-diastolic pressure are ≤ 15 mmHg, the patients are investigated using a saline load (500 ml of serum in 10 minutes) to exclude post-capillary causes of the PH, defining in that case occult PVH (Fox et al, 2013).

According to the recent guidelines, cardiac catheterisation is recommended to confirm the diagnosis of PAH, evaluate the severity, and when PAH specific drug therapy is considered. In the follow up it should be performed for confirmation of efficacy of PAH-specific drug therapy and for confirmation of clinical deterioration and for the evaluation of the effect of treatment escalation and/or combination therapy (Sitbon et al, 2005). A longitudinal study investigating survival, risk factors and causes of death in a cohort of patients with SSc without severe pulmonary fibrosis or severe left heart disease at baseline, showed that PAH increased the mortality risk in patients with SSc, suggesting that a yearly echocardiographic screening should be performed in order to make an early diagnosis (Hachulla et al, 2009).

Subclinical PAH may be evaluated through exercise echocardiography, measuring PAP during exercise and allowing to differentiate physiologic from altered PAP responses; this may identify patients that may develop

PAH (Pignone et al, 2007). This tool is under development in order to standardize the testing and determination normal values for controls but a recent report showed that exercise echocardiography may be very helpful to identify a subset of SSc patients with an inappropriate exercise-induced increase in PASP and early signs of right ventricular dysfunction that can relate to very early PAH (D'Alto et al, 2011).

A multicentre longitudinal study on a large cohort of SSc patients has further highlighted the importance of cardiac catheterisation to confirm the diagnosis of PAH; in this study cardiac catheterisation has been performed in patients in which PAH was suspected both on cardiac echo-Doppler (VTR 2.8-3.0 3.0 meters/second) associated with unexplained dyspnoea or only cardiac echo-Doppler with VTR of >3.0 meters/second. Using this algorithm the incidence of PAH was estimated to be 0.61 cases per 100 patient-years (Hachulla et al, 2009). Cardiac catheterization allows also the identification of risk factors of mortality in SSc PAH: in fact measures of RV function (SVI), pulmonary vascular compliance (SV/PP) and pulmonary vascular resistance (PVR), have been found to be strong predictors of survival (Campo et al, 2010).

The determination of the most appropriate indications for RHC in SSc patients is still an issue. But this is of importance since accurate and regular screening for PH in high risk SSc patients is paramount to improve early PH diagnosis, which may improve prognosis and optimise therapy. A Delphi technique among experts has raised the following data with three domains containing eight tools to be taken into account for referring the patients for RHC (Avouac et al, 2014): clinical (progressive dyspnoea over the past 3 months, unexplained dyspnoea, worsening of WHO dyspnoea functional class, any finding on physical examination suggestive of elevated right heart pressures and any sign of right heart failure), echocardiography (systolic pulmonary artery pressure >45 mm Hg and right ventricle dilation) and pulmonary function tests (diffusion lung capacity for carbon monoxide <50% without pulmonary fibrosis).

Discriminatory variables for identifying PAH have also been investigated through a large cross-sectional study of 466 patients (SSc for >3 years of disease duration and predicted pulmonary diffusing capacity for carbon monoxide <60%) all evaluated by a large set of non-invasive parameters and also all by RHC. Some parameters previously identified as associated with of PAH were confirmed, such as FVC/DLCO, telangiectasias, ACA, NTproBNP, right axis deviation on ECG, serum urate was raised as a new parameter, and several echocardiography variables were identified. The authors combined the data to provide a 6 simple assessment in Step 1 of the algorithm to determine referral to echocardiography and then, after adding two echocardiographic variables, to determine referral to RHC (Coghlan et al, 2013). The DETECT algorithm for PAH detection in SSc is a sensitive and non-invasive tool which, it minimises missed diagnoses and can identify milder disease.

To assess the severity of PAH WHO functional class remains a powerful predictor of survival. The New York Heart Association functional classification has been recently modified as shown below:

Class I: Patients with pulmonary hypertension but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnoea or fatigue, chest pain, or near syncope.

Class II: Patients with pulmonary hypertension resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity causes undue dyspnoea or fatigue, chest pain, or near syncope.

Class III: Patients with pulmonary hypertension resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes undue dyspnoea or fatigue, chest pain, or near syncope.

Class IV: Patients with pulmonary hypertension with inability to carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnoea and/or fatigue may even be present at rest. Discomfort is increased by any physical activity.

For objective assessment of exercise capacity, the 6-minute walking test (6MWT) is technically simple, inexpensive and well standardized. However, this criterion has not been fully validated in PAH associated with SSc (Avouac et al, 2010). This test evaluates the distance walked, dyspnoea on exertion (Borg scale) and finger O₂ saturation. Reduced walking distances with O₂ desaturation indicate impaired prognosis in PAH (Miyamoto et al, 2000 ; Paciocco et al, 2001). The disadvantages of this test is that is influenced by body weight, gender, height, age, and patient motivation and also by the systemic component of SSc; indeed myalgia, fatigue, arthritis, calcinosis and also interstitial lung and primary heart disease can influence walking test than does not reflect conversely to idiopathic PAH only lung vessel involvement and secondary heart disease (Avouac et al, 2008).

For PAH diagnosis, biochemical markers are a non-invasive tool for assessment and monitoring of right ventricular dysfunction in patients with PH. Brain natriuretic peptide (BNP) is released from myocardium in response to wall stress and induces vasodilatation and natriuresis. ProBNP is a high molecular weight precursor that is cleaved into biologically inactive N-terminal segment (NTproBNP) and the proper low molecular weight BNP. NT-proBNP has a longer half-life and a better stability both in circulating blood and after sampling are for that reason it is used as a biomarker that reflects the severity of RV dysfunction. Several papers have highlighted good diagnostic and prognostic values of this biomarker (Williams et al, 2006 ; Allanore et al, 2009 ; Steen et al, 2003 ; Allanor et al, 2008).

In addition to the mandatory early diagnosis, many groups are working on the prediction of subsequent development of SSc-PAH. The more robust data have been shown for DLCO and DLCO/VA as these parameters slightly decline several years before the occurrence of PAH and thus may help for risk stratification of SSc patients (Allanore et al, 2008). NT-proBNP may also be helpful in this context and genetic markers may add to the prediction (Manetti et al, 2011 ; Wipff et al, 2010).

IV. 5 Cardiac involvement

Cardiac involvement is common in SSc and contributes to symptoms such as shortness of breath, fatigue, and palpitations (Desai et al, 2011). The heart is often sub-clinically affected by fibrosis involving both the myocardium and the conducting system. This involves both ventricles with a “patchy” distribution and can be distinguished from that occurring in atherosclerotic coronary artery disease by a number of histological features, such as the absence of a link to any single coronary artery and of typical hemosiderin deposits and involvement of the subendocardial layers (Bulkley et al, 1976). SSc heart disease has been shown in up to 80% of SSc patients, and it may be classified as primary or secondary to other organs involvement, mainly lung involvement. SSc-heart disease is often asymptomatic for a long time and, when recognized, is associated with a poor prognosis (Ferri et al, 2002).

Cardiac involvement in SSc is likely to result from the general pathogenetic mechanism(s) thought to play a role in the disease. A “myocardial Raynaud’s phenomenon” involving unaltered small arteries has been hypothesized, but conflicting results have been reported. On the one hand, reversible perfusion defects have been detected in a significant percentage of SSc patients. On the other hand, coronary vasodilator reserve has been found to be markedly reduced in SSc. Nevertheless, reproducible data have shown that primary heart disease relates to microcirculation impairment with abnormal vasoreactivity, with or without associated structural vascular abnormalities; therefore, reversibility maybe seen at early stage but it decreases with the progression of the disease and may at advanced stage reduce coronary reserve.

Autonomic neuropathy in SSc has been reported by various authors using conventional laboratory tests (Ferri et al, 1997). Tachyarrhythmias are excessively rapid and irregular heartbeats. They usually do not cause any symptoms, but they are often fatal, and SSc patients with heart involvement are susceptible to them (Kostis et al, 1988). The worst prognosis in severe cardiac arrhythmias is significantly more frequent in those patients with both skeletal and cardiac muscle involvement (Follansbee et al, 1993).

Early recognition of cardiac involvement and diagnosis of cardiotoxicity allow early treatment, prevention of cardiomyopathy and improvement in prognosis. Thus, a thorough heart-function screening and appropriate follow-up monitoring are mandatory for all SSc patients.

Table 8. Summary of the Cardiac involvement symptoms, mechanisms and tools for assessment

	Symptoms	Mechanisms	Assessment
Pericardium	Chest pain Shortness of breath Palpitations	Inflammation	Echocardiography EKG
Myocardium Heart cavities	Shortness of breath Exercise intolerance Coughing or wheezing Oedema High heart rate	Ischemia Fibrosis Inflammation Left or right sided heart failure	Echocardiography Natriuretic peptides Radionuclide ventriculography Cardiac catheterisation MRI
Valves	NA	NA	NA
Electrical system	Syncope, dizziness irregular and unreliable heart beats Palpitations Cardiac arrest	Conduction problem Arrhythmia	EKG 24h-Holter

The screening consists of various simple, non-invasive investigations:

-physical examination

-electrocardiogram that may confirm conduction abnormalities and arrhythmias; a 24 hour monitoring should be performed since the incidence and prevalence of ECG disturbances increases when the patients are monitored with 24-h ambulatory ECG.

-chest X ray to investigate pericardial effusion and/or alteration of cardiothoracic ratio.

-Doppler 2-dimensional echocardiogram that provide information left ventricular

ejection fraction (LVEF), diastolic function, tricuspid gradient, pulmonary acceleration time, right ventricular diameter and pericardial effusion, wall motion and the possible presence of PAH.

With improved echocardiographic techniques including the use of Doppler tissular indexes, increased awareness of diastolic dysfunction and primary right ventricle involvement in SSc has been reported together with more accurate assessment of systolic functions. Therefore, including tissular Doppler is highly recommended to assess heart function (Meune et al, 2008). Diastolic dysfunction has emerged as a critical concern and may be frequent in SSc patients; it can lead to post-capillary pulmonary hypertension that requires specific therapy.

Indeed, in SSc patients differentiation between pre- and post-capillary pulmonary hypertension (PAH versus pulmonary venous hypertension-PVH) is sometimes difficult with commonly borderline patients. A study based

on 107 SSc patients of whom 53 out of 107 patients had pulmonary hypertension demonstrated the input of performing a fluid challenge (500 ml of serum in 10 minutes) and also of measuring left ventricular end-diastolic pressure (Fox et al, 2013). Indeed, after considering the resting and post-fluid-challenge measurements, 11 PAH patients were reclassified as occult PVH. It is therefore highly recommended to add to the assessments a fluid challenge and to add sometimes a left heart catheter to measure left ventricular end-diastolic pressure in addition to the wedge pressure, to accurately identify PVH.

Asymptomatic, mild pericarditis is common in SSc and does not require specific treatment in the large majority of patients. In the case of recurrent or severe effusion, anti-inflammatory drugs may be required. Renal as well as cardiac monitoring is critical in such cases since pericarditis may be associated with scleroderma renal crisis, cardiac arrhythmias, pulmonary arterial hypertension and overall progression of the disease.

NT-ProBNP may be useful for the diagnosis of cardiomyopathy because its concentration is altered in patients with myocardial structural impairment, even if asymptomatic, while troponin I is an accurate index of myocytolysis (Mady et al, 2008). It allows the detection of any abnormal strain in the heart and identifies patients who need more in depth cardio-pulmonary investigations in order to establish the cause.

When needed, additional tests may be performed, including long-term ambulatory electrocardiographic recording, assessment of cardiopulmonary performance by the six-minute walking test or cardiopulmonary stress test, cardiac catheterization (mandatory to confirm and better estimate PAH), cardiac magnetic resonance imaging, and nuclear studies of myocardial function and perfusion (Allanore et al, 2008). In particular Tc-99 SPECT using vasodilators (dipyridamole) allows to demonstrating the presence of inducible ischemia. Dipyridamole causes vasodilation through the increase of adenosine locally. This vasodilation occurs in healthy arteries, whereas stenosed arteries remain narrowed. This creates a "steal" phenomenon where the coronary blood supply will increase to the dilated healthy vessels compared to the stenosed arteries. Cardiac MRI allows the evaluation of coronary reserve and may also demonstrate the presence of inflammatory oedema or fibrosis; it is the examination of choice when myocarditis is suspected such as in overlap syndrome. Furthermore, contrast enhanced-cardiac MRI showed in asymptomatic SSc patients with long-standing disease the presence of myocardial fibrosis unrelated to coronary arteries distribution without sub-endocardial layer involvement, suggesting a subclinical heart involvement (Di Cesare et al, 2013).

The following cardiac diagnostic work-up for investigations of electrophysiological disturbances in SSc patients has been proposed (Table 9) (Vacca et al, 2013)

Table 9: cardiac diagnostic work-up for investigations of electrophysiological disturbances

Clinical manifestations	Electricophysiological assessment	Heart assessment

IV.6 Kidney involvement

Kidney involvement is often clinically silent. It may progress slowly toward renal failure and thus heavily influence prognosis. In some cases, breakdown of the renal system may be abrupt, without any sentinel symptom.

Sudden onset of high blood pressure and kidney failure is known as scleroderma renal crisis (SRC). Patients with diffuse cutaneous (DC) involvement, particularly those with early, rapidly progressive skin thickening and serum anti-RNA polymerase III antibody, are at highest risk to develop SRC (128). The typical presentation is that of a stable patient who abruptly develops severe arterial hypertension accompanied by headache, visual disturbance, seizures, congestive heart failure, pericardial effusion, microangiopathic haemolytic anaemia, thrombocytopenia and accelerated oliguric renal failure. The optic fundi show acute hypertensive changes, including haemorrhages and exudates.

Other findings include microscopic haematuria and proteinuria; occasionally RBC casts are seen in the urine (Phan et al, 1999 ; Steen, 1996 ; Lee et al, 2004). The plasma renin level is extremely high, as found in malignant essential hypertension. Renal biopsy characteristically shows changes in the small interlobular and arcuate arteries. The earliest change is intimal oedema, followed by an intense proliferation of intimal cells increased mucopolysaccharide deposition. Lymphocytes and other mononuclear cells are absent.

Fibrinoid necrosis in the vessel walls or sub intimal location is typical of severe cases in small arteries.

This usually occurs in patients with diffuse scleroderma, resulting in kidney failure within a few days. Thus, to detect sudden kidney failure promptly, daily at-home monitoring of blood pressure

is recommended for SSc patients, and particularly for those with diffuse scleroderma, even if they do not have high blood pressure or other renal symptoms.

Chronic kidney disease other than renal crisis is not well described. Kidney abnormalities such as proteinuria, hypertension, or abnormal serum creatinine does not predict future renal crisis. It has been presumed that such abnormalities reflect the vasculopathy that occurs pathologically in patients with scleroderma even in the absence of renal crisis. Colour Doppler ultrasonography can confirm the early reduction of renal arterial blood flow in patients with SSc who have no clinical sign of renal involvement. Abnormal findings on renal function tests (serum creatinine, creatinine clearance, 24-hour proteinuria) may be observed at a later stage (Kovalchik et al, 1978) of the disease. It has also been demonstrated that most patients with SSc cannot increase renal filtration under the challenge of a protein overload. This defective renal response to the amino acid load test sustains the concept of the prevalence of vasoconstrictor over vasodilating factors in the kidney of these patients (Livi et al, 2002).

IV.7 Musculoskeletal involvement

Many patients may develop musculoskeletal symptoms as an early sign of the disease or during the course of their illness. Manifestations may include varying degrees of rheumatic complaints ranging from arthralgias to frank arthritis or bony lesions. Musculoskeletal involvement has been shown to strongly contribute to disability and impaired quality of life in SSc, reducing the performance of everyday occupation (Baron et al, 1982 ; Mau et al, 2005 ; Brower et al, 2004 ; Poole et al, 2000 ; Poole et al, 1991).

IV.7.1 Joint involvement

IV.7.1.1 Prevalence

Joint involvement has been described as an initial manifestation in 12% to 65% of SSc patients with SSc and as an eventual manifestation in up to 46% to 97% of patients (Poole et al, 1991 ; Tuffanelli et al, 1961). The systematic cross-sectional examination of the EUSTAR (EULAR Scleroderma Trials and Research) registry, including more than 7,000 patients, identified synovitis in 16% (1191/7286) of SSc patients, underlining that a synovial involvement may not uncommonly occur in SSc (Avouac et al, 2010). The point prevalence of joint contracture, resulting from joint destruction turning into ankylosis and fibrotic changes in the skin, was 31% (2264/7286) in this database. The latest EUSTAR data regarding respective prevalence of musculo-skeletal symptoms are provided in figure 14. These data of prevalence have been subsequently confirmed in the recent analysis of EUSTAR database (table 5).

Recently, a preliminary study included 45 consecutive patients with SSc using ultrasonography (Cuomo et al, 2009). Joint effusion was found in 22 (49%) SSc patients and synovial proliferation in 19 (42%), which was associated with a power Doppler in 11 of them. In this study, the prevalence of synovitis as detected by

ultrasounds was found to be significantly higher than that found by clinical examination. Another series confirmed that articular involvement is underestimated by a single clinical examination (Elhai et al, 2012). It showed that synovitis and tenosynovitis were more frequently detected with US (46% and 27%, respectively) than with clinical examination (15% and 6%, respectively; $P < 0.01$ for both comparisons). Furthermore, it demonstrated that when inflammation was detected (57% of synovitis), it was mostly of weak intensity (Doppler grade 1), and that tenosynovitis could be either inflammatory or fibrotic (with layered appearance) and finally, that, calcifications could be detected in about half of the patients.

Magnetic resonance imaging (MRI) is also a very promising tool to detect synovitis. Hand inflammatory joint disease has been assessed by MRI in 17 patients with history of joint pain or swelling (Low et al, 2009). Ten patients had inflammatory MRI findings with synovitis ($n=8$), joint effusion ($n=7$) or tenosynovitis ($n=8$). In line with the progresses made in rheumatoid arthritis, these tools are under development to better evaluate and manage arthritis and tenosynovitis in SSc.

IV.7.1.2 Characteristics

Arthralgia is among the most frequent presenting symptoms of SSc. True joint inflammation may occur and be the source of initial diagnostic confusion. The onset may be acute or insidious, oligoarticular, or polyarticular in pattern. The course of the joint manifestations is either intermittent or chronic remittent. Clinical findings are often minimal at the onset, aside from features that may betray the presence of early SSc. Some patients may exhibit localized joint tenderness, or swelling, and joint effusion may be detectable although they are usually mild.

The analysis of the EUSTAR database revealed that synovitis was present in SSc patients in all disease stages. However, patients with synovitis and early disease (date of first non-Raynaud symptom < 5 years) were more likely to experience diffuse cutaneous thickening. The likelihoods of severe vascular (elevated systolic pulmonary artery pressure above 40 mmHg) and muscular (muscle weakness) involvement were higher in patients with synovitis, regardless to their cutaneous subset or their disease duration (Avouac et al, 2010). Thus, synovitis could be a risk factor of bad prognosis in SSc. Two recent prospective cohort studies including patients from the EUSTAR database have identified joint synovitis as a predictor of disease progression. The first study included 1,301 SSc patients with disease duration ≤ 3 years at inclusion and with a follow-up of at least 2 years (mean follow-up : 4.5 ± 2.2 years) (Avouac et al., 2014). Joint synovitis, detected by clinical examination, was independently predictive of the worsening of the modified Rodnan skin score ($\geq 30\%$ and ≥ 5 points) and of the further occurrence of new ischemic digital ulcers and decreased left ventricular ejection fraction. The second study was performed on 637 SSc patients with the diffuse cutaneous subset (Maurer et al., 2014). Joint synovitis was also identified in univariate and multivariate analysis as a predictor for progressive skin fibrosis. Using a second validation cohort of 188 dcSSc patients, joint synovitis were confirmed

as independent predictors of progressive skin fibrosis within 1 year. Taken together, the results of these two studies support that synovitis, an easily detected clinical marker may be useful for the risk stratification of SSc patients.

The presence of synovitis may be also related to an overlap with rheumatoid arthritis (Avouac et al, 2006 ; Cohen et al, 1982 ; Armstrong et al, 1982 ; Baron et al, 1982). Recent data support that overlaps of SSc and rheumatoid arthritis is very unusual. The prevalence of SSc-rheumatoid arthritis overlap seems close to 1-5% and its incidence is 5% (Avouac et al, 2010). Rheumatoid factor positivity may occur in about 30% of SSc patients. This test seems non-specific and do not serve to distinguish SSc patients with musculoskeletal manifestations from those not so affected. The search for anti-CCP antibodies might be of great help in the identification of the rare cases of SSc-RA overlap.

IV.7.1.3 Evaluation of structural damages

Many distinctive radiographic abnormalities have been recognized in patients with SSc. The frequency of hand radiographic erosions is estimated between 5% and 40% (Avouac et al, 2006 ; Blocka et al, 1981 ; La Montagna et al, 2005 ; Koutaissoff et al, 2011 ; Avouac et al, 2011 ; La Montagna et al, 2002). Joint space narrowing is not uncommon in SSc; its point prevalence on X-Ray has been reported to be about 30%, with a predominant involvement of DIP joints. Joint space narrowing has been found with ultrasonography in 8/45 (18%) SSc patients (Cuomo et al, 2009).

Modern techniques such as ultrasound and magnetic resonance have also been used to describe structural articular lesions. In the two studies using MRI, hand erosions were detected in 16% (6/38 patients) and 41% (7/17 patients) (Low et al, 2009; Allanore Y et al, 2007). In a recent controlled study involving 120 patients, erosive arthritis, as defined by the occurrence of both erosions and joint space narrowing, was found in 22 (18%) SSc patients (Avouac et al, 2006). The five-year longitudinal follow-up of these patients, with a systematic examination of dual time-point X-Rays, showed a total radiographic progression of erosive arthritis in 24 (23%) patients with SSc (Avouac et al, 2011). No independent predictor of the progression of erosive arthritis has been identified in SSc. This lack of predictive factor for erosive arthritis might be related to the multifactorial aspects of SSc arthropathy.

Figure 15: prevalence (% positive patients) of musculo-skeletal manifestations throughout 11318 registered SSc patients (unpublished data, Database extraction May 2014)

IV.7.2 Soft tissue, bone, and muscular involvement

In the EUSTAR database, the point prevalence of tendon friction rubs, defined as a leathery, rubbing, “squeaking” sensation detected as the tendon was moved actively or passively, was 11% (802/7286 patients) (Avouac et al, 2010). Rodnan and Medsger described this finding as “leathery crepitus” on palpation of the knees, wrists, fingers and ankles during motion in 19 of 53 patients (Rodnan et al, 1968). In the leg, tendon rubs are usually localized to the tibialis anterior, or less frequently, the peroneus muscles. In the forearm the source of this rub is usually the tendons of the flexor or extensor muscles, immediately proximal to the wrist. Median nerve compression with carpal tunnel syndrome may occur, the result, presumably of changes in the tendon sheaths beneath the transverse carpal ligament.

The prevalence of tendon involvement has been assessed by MRI in a preliminary study performed on 17 patients; eight had tenosynovitis, either of flexor (n=7) or extensor (n=3) tendons (Low et al, 2009). The frequency of tendon involvement has not yet been assessed by ultrasounds. However, this examination, as well as MRI, might be useful to discriminate fibrotic tenosynovitis secondary to fibrous deposits on the surface of the tendon sheaths and inflammatory tenosynovitis.

Tendon involvement is more prevalent in patients with the diffuse cutaneous subset and early disease. It is also associated with signs of severe vascular, muscular, renal involvement and decreased survival (Steen et al,

1997). In particular, the cross-sectional analysis of the EUSTAR database highlighted the independent association in multivariate analysis between tendon friction rubs and digital ulcerations, muscle weakness, pulmonary fibrosis on plain chest X-ray and proteinuria detected with a urinalysis dipstick. Another cohort showed that early DcSSc patients with TFRs have a about 2-fold risk of developing renal crisis and cardiac or gastrointestinal disease complications, even after adjustment for other known risk factors. Furthermore, even after age and gender adjustment, TFR cases were 1.8 times more likely to die at 5 years (95% CI 1.21–2.58, $P < 0.003$) (Doré et al, 2013). The recent prospective analysis of the EUSTAR database has also confirmed that tenosynovitis was an independent predictor of skin progression and of the further occurrence of scleroderma renal crisis (Avouac et al., 2014). Altogether, these results highlight that tendon friction rubs are an important physical finding, because they often precede widespread skin thickening and can be considered as a sign highly predictive of bad outcome.

Subcutaneous calcifications may be seen as a hallmark of SSc in comparison to other connective tissue disorders. Recent studies using consecutive X-rays or ultrasonography have allowed to clarify its point prevalence, which is about 20 to 30% (Avouac et al, 2006 ; Blocka et al, 1981 ; La Montagna et al, 2005 ; Koutaissoff et al, 2011; Avouac et al, 2011 ; La Montagna et al, 2002). The incidence of radiographic calcinosis after a median duration of 5 years is about 14% (Avouac et al, 2011). Calcinosis may also occur in other locations such as feet, knees and legs. It is noteworthy that it predominates at sites of repetitive stress or pressure, suggesting that trauma and/or ischemia may contribute to its pathogenesis as this is well known for shoulder calcifications. This has been strengthened by recent cross-sectional series showing a link between calcinosis, acro-osteolysis and digital ulcerations (Avouac et al, 2006). In addition, digital ulcers have recently been identified as independent predictors of radiographic progression of calcinosis.

Osseous resorption is a common finding and acro-osteolysis occurs in about 20% of the patients. Further other locations may be involved such as carpal bones, radius, ulna, ribs, mandible, clavicle, humerus or cervical spine (Mugino et al, 2006). Calcinosis and digital ulcers were recently identified as independent predictors of the radiographic progression of acro-osteolysis (Avouac et al, 2011). These data suggest that patients with severe digital vasculopathy are more at risk to experience radiographic progression of bone resorption and further support the role of vascular injury playing a critical role in such lesions, possibly due to repeated vasospasm, as previously suggested (Scharer et al, 1969). Other pathogenic hypotheses, such as vitamin D deficiency, have also to be taken into consideration, although they are still a matter of debate (Braun-Moscovici et al, 2008 ; Vacca et al, 2009).

Osteoporosis had not been the matter of many studies probably because SSc has many complications and also because it is not a very inflammatory disease. Nevertheless, among 1712 Taiwanese SSc patients (78% female, mean age 50 years) with a median follow-up of 5.2 years, 54 patients developed vertebral fractures, 17 hip fractures, and 7 radius fractures (IR: 6.99, 2.18 and 0.90 per 1000 person-years, respectively). Compared with

the controls, the incidence rate ratios (IRRs) (95% CIs) among SSc patients were 1.78 (1.30 to 2.39, $p<0.001$) for vertebral fractures and 1.89 (1.05 to 3.22, $p=0.026$) for hip fractures. The IRRs for overall OFs were 1.74 (1.32 to 2.27, $p<0.001$) for women and 1.06 (0.33 to 2.66, $p=0.856$) for men. Multivariable analyses indicated that older age, being female, using daily prednisolone equivalent to >7.5 mg, and bowel dysmotility treated with intravenous metoclopramide are associated with osteoporotic fracture (Lai et al, 2015). Therefore, osteoporosis in female patients should be a concern in SSc patients.

SSc related myopathy is frequent in SSc, involving up to 80% of SSc patients (Clements et al, 1978). This myopathy is often mild, non-progressive, with minor proximal weakness, and normal or slight elevation of creatine kinase (CK). The overlap between inflammatory myositis and SSc is less frequent, with a prevalence of about 5% (Tuffanelli 1962). This manifestation is characterized by proximal weakness, elevated CK typical EMG and histology of inflammatory myositis and presence of Anti-PmScl antibodies (Ranque et al, 2009).

V. Disease activity

In the assessment of SSc patients, the evaluation of different clinical features should be assessed, from diagnosis to clinical response to treatments. Defining disease activity in SSc could not be easily done using a single variable: i. patients may experience a heterogeneous course, from relative benign and indolent forms to rapidly progressive forms; ii. SSc flares can be difficult to separate from quiescent disease; iii. the two main morphological manifestations of the disease (interstitial fibrosis and vascular occlusion) may both reflect activity, which is still potentially reversible and/or damage, classically irreversible; iv. validated biological markers reflecting disease activity are still lacking. In 2001, 11 SSc disease activity variables were identified and a preliminary activity index was developed, which has been used to assess disease activity in subsequent studies. The validity of this activity index is supported by its correlation with the physician global assessment of activity of the Canadian Scleroderma Research Group, its association with anti-Scl70 titre and its role as the main predictor of the scleroderma phenotype of SSc skin fibroblasts (Valentini et al, 2011). However, it displayed some limitations mainly due to the procedure underlying its development such as most patients had long disease duration and the number of missing values was high. On these bases, more recently, a revised SSc activity index has been developed. Specifically, a weighted 10-point activity index was identified and validated: Δ -skin=1.5 (Δ =patient assessed worsening during the previous month), mRss >18 =1.5, presence of digital ulcers=1.5, presence of tendon friction rubs=2.25, CRP >1 mg/dL=2.25 and DLCO predicted $<70\%$ =1.0. A cut-off ≥ 2.5 was found to identify patients with active disease. To date, changes in the index paralleled those of Medsger severity score (Valentini et al, 2017). The revised EUSTAR index contains tendon friction rubs and increased serum CRP that have been associated with reduced survival and worsening of skin fibrosis (Avouac et al, 2016; Muangchan et al, 2012). Similarly, to the previous one, the revised EUSTAR index contains mRss, digital ulcers and DLCO. mRss reflects the degree of skin sclerosis and has long been considered a measure of disease activity in SSc (Walker et al, 2010). Nevertheless, the persistence of defined skin sclerosis is not

consistent with inactive disease. Digital ulcers are clearly related to vascular disease activity and have been recently found to predict the occurrence of new digital ulcers during follow-up and to be associated with cardiovascular morbidity and decreased survival (Mihai et al, 2016). A decreased DLCO can depend on both vascular and interstitial lung disease. In the absence of pulmonary hypertension, however, it has been found to provide the best overall estimate of HRCT-measured lung fibrosis (Valentini et al, 2017).

VI Treatment

VI.1 Overall treatment

Severe forms of the disease and rapidly progressive diffuse SSc in particular, are associated with significant mortality (estimated at 40%-50% in 5 years) secondary to pulmonary, cardiac, and renal involvement (Medsger et al, 1971 ; Altman et al, 1991). No proven effective therapy exists to prevent disease progression. The perceived failure of immunosuppressive treatments in the reversal of established fibrosis suggests that once initiated, the fibrotic process becomes independent of the immune drive and continues as an autonomous process.

Blinded randomized clinical trials of D-penicillamine failed to demonstrate a clinically significant effect (Clements et al, 1999). Low-dose oral methotrexate showed beneficial effects on skin thickening, but not on organ dysfunction, in a small placebo-controlled crossover study (Van den Hoogen et al, 1996).

Cyclophosphamide (Cyc) has been shown to improve skin thickening, stabilize pulmonary function, and increase survival in non-randomised trials (Akesson et al, 1994 ; White et al, 2000). Although the efficacy of Cyc is considered moderate, this is currently the only drug with proven efficacy in SSc interstitial lung disease and for that reason has been recommended as the drug of choice in progressive lung involvement (Avouac et al, 2009; Kowal-Bielecka et al, 2009).

Biologic therapies target molecules involved in the mechanisms of the immune system, such as cytokines (TNF- α , IL-6), immune cells (B cells) or co-stimulation molecules (CTLA4). Several of these pathways could contribute to SSc and the experience learned from other immune diseases promote the evaluation of biologics in SSc. Several trials are underway but some preliminary data highlight potential benefit. In a double-blind, placebo-controlled, phase 2, proof-of-concept study, the effect of tocilizumab (TCZ-162 mg SC weekly) was investigated in 87 DcSSc patients ≤ 5 years of disease duration, with modified Rodnan skin score (mRSS) 15-40, and elevated acute-phase reactants. At week 24, a favourable but not statistically significant effect of TCZ over PBO on mRSS was noted (-3.9 vs -1.2 ; adjusted mean difference, -2.7 [95% CI: -5.85 , 0.45], $p=0.09$). At week 48, a numerically larger change was noted in the TCZ vs PBO arm (-6.3 vs -2.8 ; adjusted mean difference, -3.6 [95% CI: -7.23 , 0.12], $p=0.06$). There were numerically greater improvements in the TCZ arm than in the PBO arm for patients reported outcomes (HAQ-DI, patient global assessment and FACIT-fatigue) at week 48. Of interest, fewer TCZ vs PBO patients showed a decline in forced vital capacity. Adverse events (AEs)/serious AEs occurred

in 98%/33% of TCZ and 91%/34% of PBO patients by week 48. One death occurred in the PBO arm and 3 deaths in TCZ patients by week 48; all were unrelated to study drug except for a fatal lung infection in one TCZ patient. Overall, the effect of TCZ on skin sclerosis, PROs, and pulmonary function and the observed safety profile suggest a positive risk/benefit profile for TCZ in SSc (Khanna et al, 2016).

An elegant study allowed by the EUSTAR database compared RTX treated versus untreated matched-control SSc patients. It demonstrated improvement of skin fibrosis and prevention of worsening lung fibrosis, supporting the therapeutic concept of B cell inhibition in SSc (Jordan et al, 2014). This supports the performance of a randomised trial to determine whether anti-CD20 therapy might be efficient against the fibrotic process in SSc.

A first double-blind placebo controlled randomized clinical trial evaluating IV immunoglobulins included 63 dcSSc patients. MRSS at 12 weeks showed no significant difference between the IVIg and placebo, but when re-administering IVIg to those patients who showed mRSS improvement ≥ 5 points, a significant difference in mRSS change was seen between double and single IVIg administrations. Therefore, although the primary endpoint was not achieved, repeated administration of IVIG may be effective for skin sclerosis (Takehara et al, 2013) and another trial is ongoing (NCT01785056).

In the past decade, intense immunosuppression followed by autologous stem cells transplantation (HSCT) has emerged as a new therapeutic procedure for patients affected by severe SSc that is refractory to conventional treatments (Tyndall et al, 2003). A phase I-II trial showed improvement in the skin score ($>25\%$ in 69% of the patients), stabilization of lung function and pulmonary pressure, and no occurrence of renal crisis after the treatment (Farge et al, 2002). The initial procedure-related mortality observed was particularly elevated (17%), probably owing to the already advanced organ damage of most participants (Farge et al, 2004). The results of the ASTIS trial, a randomized controlled trial of autologous HSCT vs. pulse monthly cyclophosphamide, showed from 156 early DcSSc patients better event-free survival and overall survival and clinically meaningful improvements (skin, forced vital capacity), although this is balanced by a high toxicity (in the HSCT arm, 8/79 patients died of treatment-related causes in the first year) (van Laar et al, 2014). Selection criteria for patients who might benefit from such procedure remain to be determined.

VI.2 Treatment of specific organ involvements

VI.2.1 Gastro-intestinal involvement

Treatment of oesophageal disease in SSc is based, first of all, on modifications in lifestyle. Gravity plays an important role in controlling reflux. To minimize the possibility of heartburn, it is recommended that an upright posture be maintained until a meal is digested and avoid exertion after a meal (Table 7). The medications prescribed to treat oesophagus dysmotility and reflux are promotility agents, H2 blockers, and

proton pump inhibitors. Despite the lack of specific RCT, PPI have been recommended for the prevention of SSc-related gastro-oesophageal reflux, oesophageal ulcers and strictures. Prokinetic drugs should be used for the management of SSc-related symptomatic motility disturbances (dysphagia, GERD, early satiety, bloating, pseudo-obstruction) (Emmanuel et al, 2004 ; Tiev et al, 2011).

Because these agents work in different ways, combination therapy employing two or more of these drugs may be especially helpful in controlling symptoms (Table 7).

Malabsorption and enterocyte dysfunction further degrade the health of the gut by reducing local and systemic nutrition delivery. When bacterial overgrowth is caused by slow transit through the small bowel, broad-spectrum antibiotics are indicated for a few days per month, and patients should reduce or avoid fats and fibre in their diet in an effort to reduce abdominal symptoms such as constipation and distension. The bowel can remain atonic and nonpropulsive, causing fermentation and bacterial overgrowth. In early phases, treatment with octreotide can stimulate small bowel function, helping to reduce bacterial overgrowth.

Table 10: Treatments for gastro-intestinal involvement

GI	Intervention
Esophagus	Lifestyle modifications : avoiding taking food late, fat foods and chocolate (reduce LES pressure), spicy foods and alcohol (heartburn), cessation of smoking -> multiple small meals -> raising the head of bed Acid suppressive medication: proton pump inhibitors: reduce symptoms, improve Phmetry, heal oesophagitis
Stomach	Prokinetic agents (i.e., metoclopramide, domperidone, low-dose erythromycin) Percutaneous gastrostomy GAVE: iron replacement therapy and red blood cells transfusion, endoscopic ablation, exceptional surgical antrectomy
Intestine	Antibiotics Supportive nutrition Prokinetic agents: octreotide
Ano-rectal	Solidifying liquid feces, biofeedback and sacral nerve stimulation Surgical intervention to treat rectal prolapse or perforation

VI.2.2 Interstitial lung disease

At present, the pulmonary involvement is considered the main cause of mortality, in SSc patients. Currently, the management of SSc-ILD is related to immunomodulation. In fact, non-selective immunosuppressive drugs such as CYC and mycophenolate mofetil are still the most widely used medications (Iudici et al, 2015).

The effects of both pulses and oral Cyc on lung involvement in SSc have been reported in double-blinded placebo controlled randomized trials, where Cyc seems moderately helpful in stabilizing lung function. The

efficacy and safety of oral or pulse CYC in the treatment of SSc–ILD disease were shown in two randomized clinical trials (RCTs): the Scleroderma Lung Study (SLS) (Tashkin et al, 2006) and the Fibrosing Alveolitis in Scleroderma Trials (FAST), respectively (Hoyles et al, 2006). The SLS study showed that 1 year of oral CYC (≤ 2 mg/kg/day for 12 months followed for an additional 1 year) improved lung function, skin scores, dyspnea and health status/disability, and these effects may persist, for several months after CYC discontinuation. However, except for a sustained impact on dyspnea, all of these effects waned and were no longer apparent at 24 months. The FAST study did not show an improvement in the primary (FVC or DLCO) or secondary endpoints in the CYC group. However, for FVC, there was a trend toward statistical significance between the 2 groups. It must be pointed out that, despite of several studies support the effectiveness of CYC therapy in preventing a decline in lung function and premature death in SSc–ILD patients, recent systematic review and meta-analysis of RCTs and observational prospective cohort studies failed to confirm any clinically significant improvement in pulmonary function in SSc patients treated with CYC (Nannini et al, 2008; Poormoghim et al, 2012). Recently, SLS II, a study in which SSc–ILD patients were treated with mycophenolate mofetil for 2 years or CYC for 1 year, showed that both the treatment resulted in a significant improvement in the pre-specified measures of lung function over the 2-year course of the study. Mycophenolate mofetil was better tolerated and associated with less toxicity. However, the hypothesis that it would have higher efficacy at 24 months than CYC was not confirmed (Tashkin et al, 2016).

Although small case series and retrospective studies suggested the use of azathioprine as maintenance immunosuppressive treatment for SSc–ILD, a randomized unblinded clinical trial, comparing CYC and azathioprine (a purine analog), as first-line treatment, did not provide any evidence of efficacy for azathioprine in the treatment of SSc patients affected by ILD (Nadashkevich et al, 2006).

Pirfenidone is a pyridone showing both anti-inflammatory and anti-fibrotic effects, it has been approved for the management of patients with idiopathic pulmonary fibrosis. Pirfenidone was administered as a compassionate treatment in 8 patients with idiopathic pulmonary fibrosis and 2 patients with SSc–ILD. The drug was overall well tolerated, and although it did not improve survival, it stabilized the effects on progressive pulmonary fibrosis (Nagai et al 2002; Miura et al, 2014). Recently, the LOTUSS study, a phase II, open-label, randomized, 16-week study was designed to assess the safety and tolerability of pirfenidone in patients with SSc–ILD. The drug showed an acceptable tolerability profile that was not affected by concomitant treatment with MMF, but results about efficacy are still not available (Khanna et al 2015b).

Imatinib, a tyrosine kinase inhibitor, may be a therapeutic option for SSc patients. The open-label studies conducted to assess the safety and effectiveness of imatinib mesylate in the treatment of dcSSc showed a statistically significant improvement in FVC and also in skin thickening (Spiera et al 2011; Khanna et al, 2011; Fraticelli et al 2014).

Several alternative approaches may be considered in ILD-SSc, including B cell depletion therapies (rituximab; RTX), bosentan, anti-TGF- β antibody, anti-IL-6 antibody, anti-IL-13 antibody, and HSCT. Finally, lung transplantation may be considered but it is limited to those patients, with severe SSc-ILD, unresponsive to pharmacologic interventions and without significant comorbidities (Giacomelli et al, 2017).

VI.2.3 PAH Calcium channel blockers (such as nifedipine or diltiazem) can be effective in patients with a positive vasoreactivity test (Chaisson et al, 2013) but this is very unusual in SSc patients and therefore high dose of calcium channel blockers is exceptionally recommended.

Several endothelin antagonists are now on the market and although no trial was specifically performed in SSc-PAH, the post-hoc analyses coming from the large RCTs performed in PAH have shown some efficacy.

Bosentan, a mixed ETA and ETB endothelin receptor antagonist showed to reduce dyspnoea and improved ability to perform normal daily activities (Joglekar et al, 2006 ; Ahmadi-Simab et al, 2005). Macitentan is a dual endothelin antagonist characterized by sustained receptor binding and enhanced tissue penetration. It has demonstrated a reduction of morbidity and mortality among patients with pulmonary arterial hypertension (Pulido et al, 2013). Benefits were shown both for patients who had not received treatment previously and for those receiving therapy for pulmonary arterial hypertension at study entry. Data in SSc-PAH have not been analysed independently. Ambrisentan, a selective ETA blocker, has determined a significant improvement in exercise capacity and decrease in time to clinical worsening, along with evidence to support an improvement in WHO functional class and quality of life (Galie et al, 2005).

Other licensed therapies include PDE5 inhibitors. Sildenafil was shown to improve 6MWT, functional class and haemodynamics (mean PAP and PVR) and has been approved for the treatment of patients in NYHA class II, III and IV (Galie et al, 2005). Tadalafil, as a tablet with a recommended dose of 40 mg, is the first daily phosphodiesterase type 5 inhibitor approved to treat the disease. Tadalafil improved the walking distance, and patients receiving this drug experienced less clinical worsening, defined as death, lung transplantation, atrial septostomy, hospitalization because of worsening PAH, initiation of new PAH therapy, or worsening WHO functional class, compared to the placebo group (Oudiz et al, 2012).

Riociguat is a novel drug that stimulates soluble guanylate cyclase independently of nitric oxide and in synergy with nitric oxide. It is labelled and available in pulmonary arterial hypertension (Ghofrani et al, 2013) where it demonstrated efficacy on exercise capacity, pulmonary vascular resistance and time to clinical worsening and chronic thromboembolic pulmonary hypertension (Ghofrani et al, 2013) where it showed improvement in exercise capacity and pulmonary vascular resistance. Specific data in CTD-PAH (n=111) and SSc-PAH (n=66) suggested that the mean treatment difference between riociguat and placebo (+28 m) was lower than that observed in the overall PAH population (+36 m) (Humbert et al, 2017).

The antiproliferative agent and tyrosine kinase blocker Imatinib in patients did show in trials improvement in exercise capacity and haemodynamics in patients with advanced PAH, however, serious adverse events and study drug discontinuations were common, which did not allow the drug to be labelled in this indication.

Ventavis®, an inhaled-solution form of iloprost, is indicated for patients classified as having stage III or IV pulmonary hypertension (Olschewski et al, 2002). Severe cases still require intravenous prostacyclin analogues such as epoprostenol or iloprost. Beneficial hemodynamic effects of epoprostenol included a statistically significant decrease in pulmonary vascular resistance, mean pulmonary artery pressure and right atrial pressure, as well as a significant increase in cardiac index. However the way of administration (through a permanent indwelling central venous catheter) may favour adverse events such as infections, pneumothorax, and haemorrhage. Sudden disruption/withdrawal of i.v. epoprostenol (due to catheter/vein thrombosis and/or patient's decision) may lead to life-threatening PAH rebound. For that reason, on overall risk-to-benefit considerations, and in agreement with the current ACCP guidelines, intravenous epoprostenol is recommended for the treatment of severe, therapy resistant SSc-PAH (Badesch et al, 2000). Subcutaneous treprostinil has shown to improve the 6MWT, the dyspnoea score and hemodynamic parameters in a heterogeneous population of PAH patients. In a subgroup of connective tissue disease (50% SSc), treprostinil has shown to significantly improve the cardiac index and the fatigue-dyspnoea score and there was a trend towards improvement (Simonneau et al, 2002). Efficacy is dose related, and subcutaneous administration may be limited by infusion site reaction and pain (Simonneau et al, 2002). In a phase 3 event-driven trial, that enrolled 1156 patients with PAH in untreated patients or on top of a stable dose of an endothelin-receptor antagonist, a phosphodiesterase type 5 inhibitor, or both, selexipag (an oral selective IP prostacyclin-receptor agonist) did show its efficacy (Sitbon et al, 2015). A composite of death from any cause or a complication related to PAH occurred in 41.6% of those in the placebo group and 27.0% of those in the selexipag group. Disease progression and hospitalization accounted for 81.9% of the events. By the end of the study, 105 patients in the placebo group and 100 patients in the selexipag group had died from any cause (NS). The most common adverse events in the selexipag group were consistent with the known side effects of prostacyclin, including headache, diarrhoea, nausea, and jaw pain. SSc specific data are not available.

Combination therapy with agents that target different pathways may potentially increase the overall therapeutic effect on the mechanisms of this disease and provide additional clinical benefits. In an event-driven, double-blind study, including 500 patients in WHO classes class II or III, initial combination therapy with 10 mg of ambrisentan plus 40 mg of tadalafil (combination-therapy group) was compared to 10 mg of ambrisentan plus placebo (ambrisentan-monotherapy group), or 40 mg of tadalafil plus placebo (tadalafil-monotherapy group). The hazard ratio for the primary end point (time-to-event analysis) in the combination-therapy group versus the pooled-monotherapy group was 0.50 (95% confidence interval [CI], 0.35 to 0.72; $P < 0.001$) (Galie, et al, 2015). The adverse events that occurred more frequently in the combination-therapy

group than in either monotherapy group included peripheral oedema, headache, nasal congestion, and anaemia. This large controlled trial demonstrate that among participants who had not received previous treatment, initial combination therapy with ambrisentan and tadalafil resulted in a significantly lower risk of clinical-failure events than the risk with ambrisentan or tadalafil monotherapy. Within the participants, 187 had a connective tissue disease (118 SSc) and a similar benefit of the upfront combination therapy was observed (HR 0.432; 95% CI: 0.242, 0.771), with a reduction in hospitalisations primarily driving the treatment effect (Galie et al, 2015).

The UCLA team reported a historical cohort study to evaluate whether aggressive PAH-targeted therapy (the use of a prostanoid and prostanoid initiation within six months of the diagnostic catheterisation) could improve the outcomes of SSc-PAH. Among 251 SSc patients who underwent a RHC, 99 met RHC criteria for either SSc-PAH (n=28) or SSc-PH-ILD (n=71, defined by ILD >30% or if intermediate ILD on CT scan, associated with FVC<70%). It is of note that the initial PAH therapy was a PDE-5 inhibitor (43%) or an endothelin antagonist (45%) and that over 50% of the entire cohort was treated with at least two PH-specific therapies during the study period. Twenty-four percent of patients (1 [4%] SSc-PAH and 21 [32%] SSc-PH-ILD) started a prostanoid ≤6 months of the RHC, while an additional 24% (9 [36%] SSc-PAH and 13 [20%] SSc-PH-ILD) started a prostanoid >6 months after the diagnostic RHC. The 1-, 2-, and 3-year survival estimates were 82%, 66%, 60%, and 72%, 59%, 50% for the SSc-PAH and SSc-PH-ILD, respectively. After accounting for gender, PVR index, and ILD status, early prostanoid use remained significantly associated with improved survival (HR 1.4, p<0.01) (Volkman et al, 2014). This study confirms that survival in patients with SSc-PH-ILD is poor. This cohort suggests modestly improved survival in these patients compared with prior series and more data on early use of prostanoids such as for combination therapies are now needed.

It must be reminded that the very large majority of these data were obtained in trials including mainly idiopathic forms of PAH and that specific data on SSc-PAH patients are missing. It must also be reminded that supportive care must be offered to SSc-PAH patients (diuretics, oxygen delivery, anti-coagulants...

VI.2.4 Kidney involvement The outcome of scleroderma renal crisis is poor despite aggressive treatment for high blood pressure. SSc patients who develop high blood pressure should immediately receive ACE inhibitors to control blood pressure. ACE inhibitors can improve the prognosis, but it is still not known if they can prevent scleroderma renal crisis. Patients with loss of renal function require dialysis (Steen VD et al, 1990). It is noteworthy that four retrospective studies suggest that steroids are associated with a higher risk of scleroderma renal crisis. Patients on steroids should be carefully monitored for blood pressure and renal function (Steen et al, 1990).

VI.2.5 Digital vasculopathy Although vasculopathy is a key factor in the pathophysiology of SSc and the main cause for RP and its complications, available data suggest that SSc patients do not yet receive sufficient

vasoactive therapy. In a recent analysis of German Network for Systemic Scleroderma registry, patients were treated with vasoactive drugs in 61.1% of case mainly calcium channel inhibitors and angiotensin-converting enzyme inhibitors (Moinzadeh et al, 2016).

Nifedipine and i.v. iloprost have been shown to reduce the frequency and severity of SSc-related Raynaud's phenomenon attacks (Thompson et al, 2001). Dihydropyridine-type calcium channel blockers, usually oral nifedipine, should be considered for first-line therapy for SSc-related RP, and intravenous iloprost, or other available i.v. prostanoids, for severe SSc-related RP (Pope, 2007).

Digital ulcers, a complication of chronic tissue ischemia, need both topic and systemic treatment. Intravenous prostanoids (particularly i.v. iloprost) and nifedipine are efficacious in healing digital ulcers.

The use of Bosentan has determined fewer new digital ulcers in bosentan-treated SSc patients than in patients receiving placebo. The treatment effect was most marked in preventing the development of multiple ulcers. These encouraging results have been confirmed in a further randomised placebo-controlled clinical trial, in which bosentan demonstrated efficacy in the reduction of new digital ulcerations onset in SSc patients. In this trial bosentan appears more effective in patients with more than 3 active digital ulcers at treatment outset and this reduction is associated with improved hand function (eating and dressing). Bosentan does not appear to speed healing of digital ulcers, the cardinal ulcer persisted in 50% of all subjects for up to 24 weeks. These data suggest that chronic endothelin receptor antagonism has an important effect on peripheral vascular integrity and function in SSc (Korn et al, 2004; Matucci-Cerinic et al, 2011). Macitentan has been evaluated in 2 randomised controlled trials with 2 doses compared to placebo regarding the cumulative number of new DU at 16 weeks. Both trials failed to show efficacy. Among enrolled patients with SSc and active ischemic digital ulcers, treatment with macitentan did not reduce new digital ulcers over 16 weeks. These results do not support the use of macitentan for the treatment of digital ulcers in this patient population. It was remarkable that in this population with at least one current, or, in the past year DU, about 60% of the patients did not develop new DU during the follow-up (Khanna et al, 2016c).

The sildenafil that showed promises in observational studies failed to demonstrate its efficacy on DU healing in a randomized controlled study that involved 83 patients with a total of 192 DUs. The HR for DU healing was 1.33 (0.88 to 2.00) ($p=0.18$) and 1.27 (0.85 to 1.89) ($p=0.25$) when adjusted for the number of DUs at entry. An unexpectedly high healing rate was observed (66%) (Hachulla et al, 2015). However, a significant decrease in the number of DUs in favour of sildenafil compared with placebo was observed at W8 and W12, suggesting a sildenafil benefit.

In the treatment of SSc ulcers, a topical treatment is needed. Firstly a wash with sterile solution and disinfection of the lesion is required, then mechanical removal of fibrin, induction autolysis of necrotic tissue and induce repair is necessary in order to recreate an appropriate microenvironment (humidity). For that

reason any medication that will block the gas exchange and formation of humidity (greenhouse effect- restore the microclimate) should be avoided: “closing” the ulcers may facilitate infection that spread rapidly into the tissue, and the circulation (septicaemia). In case of infections it is necessary to identify the microbial agent through a biopsy, in order to establish a prompt systemic antibiotic treatment. Then a frequent follow-up should be considered to determine when the infection is solved, to go back to standard procedure.

VI.2.6 Musculoskeletal involvement The management of articular involvement is essentially supportive and symptomatic. For the most part, the minor rheumatic symptoms of SSc, such as arthralgias, will respond to simple non-steroidal anti-inflammatory drug treatment. Low dose corticosteroids (<10 mg/day) may also have some value for the symptomatic treatment of inflammatory arthritis or tenosynovitis. By analogy with RA, methotrexate is usually used for the treatment of inflammatory arthritis. Sub-cutaneous or intramuscular routes should be used to prevent reduced digestive absorption. Other immunosuppressive drugs may be used such as azathioprine. A pilot study performed on 7 women with SSc and severe and refractory inflammatory joint involvement has suggested the efficacy after 6 months of intravenous immunoglobulins therapy (Nacci et al, 2007). It seems reasonable to avoid TNF α inhibitors in SSc: cases of fatal exacerbation of fibrosing alveolitis have been reported in a SSc patient and also in RA patients (Allanore et al, 2006).

Very preliminary data showed in an observational study that both tocilizumab and abatacept could improve SSc-polyarthritis. Results on SSc-myopathy were less demonstrative. No trend for any change of fibrotic lesions was seen in these patients but this may relate to the exposure time and inclusion criteria (Elhai et al, 2013). Larger and randomised studies with longer follow-up are now warranted to further determine the safety and effectiveness of these drugs in SSc. Trial with tocilizumab targeting skin fibrosis in progressive patients will be finished in 2014 and trial with abatacept should start very soon.

No treatment has proven efficacy in calcinosis, which remains a critical complication to manage.

Surgery of the hand for SSc is generally considered for pain reduction, severe fixed deformities with functional limitations, ulceration and calcinosis. The goals of surgery are limited and include pain relief, repositioning the digits, providing a functional position of fusion, and in some cases modest mobilization through resection arthroplasty, to marginally improve finger function for patients with marked pre-existing limitations.

The treatment of tendon involvement is usually symptomatic and supportive, since their evolution is usually favourable after the first years of the disease course. For the most part, tenosynovitis will respond to NSAIDs and low dose of corticosteroids. Surgery may be required in the very rare cases of tendon rupture.

SSc related myopathy does not usually require any specific therapy. However, in the case of overlap between SSc and inflammatory myositis, high doses of corticosteroids and immunosuppressive may be added to the conventional treatment of SSc.

Conclusions

In the next future, the improvement of our knowledge regarding the genetic background of the disease and the molecular pathogenic pathways, involved in the susceptibility and pathophysiology of SSc, will allow us to better identify/classify patients, that are potentially good-responder to specific targeted therapies, in order to improve our skills in management of SSc patients.

SUMMARY POINTS

- In conclusion, there have been many advances over the past 10 years in management of SSc and controlled clinical trials are starting to confirm treatment effectiveness. This provides a strong platform for future advance.
- At present organ-based complications are generally more amenable to treatment than the underlying disease, in that way early detection is critical and systematic assessment mandatory
- Many controlled trials are ongoing looking primarily at skin or lung fibrosis and derive from the improvements in the understanding of the pathogenesis of the disease.

IN-DEPTH DISCUSSION I

Nailfold capillary microscopy

In systemic sclerosis (SSc), clinical and pathologic findings of vascular damage and endothelial cell activation strongly support the hypothesis of a unique vascular disease as an important and primary process. It is likely that prolonged endothelial cell perturbation and activation induced by ischemia and reperfusion may lead to dysfunction and irreversible loss of integrity, with cell detachment and persistent tissue injury. The earliest clinical symptoms of SSc are due to disturbances of the peripheral vascular system.

Nailfold capillary microscopy has an impressive cost/effectiveness ratio: it is simple, safe, non-invasive and inexpensive. In clinical practice, the skin capillaries are generally observed through an incident light microscope. However, nailfold capillary microscopy can be performed by means of a series of instruments, including the ophthalmoscope, the stereomicroscope, photomacrography and, more recently, videocapillaroscopic systems.

Videocapillaroscopic analysis is considered, at the present time, to be the most sophisticated and may also detect blood flow at the level of the microvessels.

Nailfold video-capillaroscopy (NVC) shows a variety of morphological changes including enlarged capillaries, bushy capillary formations, micro haemorrhages, and a variable loss of capillaries with or without avascular areas. Capillaroscopic patterns in SSc may vary according to the disease stage. Some studies have described the morphological aspects of vascular damage in patients with SSc by NVC, correlating these capillary abnormalities to selected characteristics of the disease. NVC is a non-invasive and safe technique that can be a diagnostic and potentially a follow-up parameter of microvascular modifications in SSc classified in the “early”, “active” and “late” NVC patterns. The principal alterations of each SSc pattern are reported in table I.

Before starting the exam patients are acclimatized for 30 min at comfortable temperature. NVC is performed using an optical probe videocapillaroscopy equipped with 100x and 200 x contact lenses and connected to image analyse software observed on a colour monitor and printed on a digital video printer.

The nailfolds of all 8 fingers are examined, (thumbs excluded), after a drop of immersion oil placed on the nailfold bed to improve the image resolution. Fingers affected by recent local trauma are not analysed. The following parameters have to be considered in SSc patients, according to previous classifications: presence of enlarged and giant capillaries, haemorrhages, loss of capillaries, and disorganization of the vascular array and ramified/bushy capillaries.

On the basis of the NVC abnormalities, SSc patients were distributed into the appropriate NVC pattern, as previously reported.

The three major NVC patterns seem to reflect the evolution of SSc microangiopathy and their recognition may be useful in assessing microvascular damage in individual patients, both at a single point and longitudinally in

time. In healthy subjects, capillary loops and capillary distribution do not change with time, and the same pattern is usually maintained.

In SSc patients the pattern of microangiopathy may change with time, but longitudinal data remain scarce so far. NVC abnormalities such as enlarged and giant capillaries are the first sign of SSc microangiopathy, but they become rare in patients with longer disease duration. On the contrary, capillary rarefaction and ramifications are rare in the early stage of SSc microangiopathy but are common in patients with longer SSc duration. Indeed, NVC patterns correlate with the duration of Raynaud's phenomenon and reflect the evolution of the disease process.

An increased vascular permeability and a reduced blood flow are observed in all NVC groups confirming previous studies. Furthermore, NVC allows, in SSc in particular, the observation of the prolonged phases of reduced or ceased capillary perfusion as a result of cold-induced peripheral vasospasm.

When SSc patients have been evaluated both with NVC and laser-Doppler Blood flowmetry (that is used to estimate cutaneous blood flow of microvessels), the blood flow changes observed with laser Doppler seem to correlate with the severity of microvascular damage in SSc as detected by NVC: when the probe was heated to 36 degrees induced a lower increase in peripheral blood flow in SSc patients with an advanced microvascular damage detected by NVC.

The NVC patterns have been correlated with different clinical aspects and manifestations of SSc, as well as with the effects of treatment, thus contributing to the overall study of the disease.

A recent study has highlighted the correlation of a quantitative videocapillaroscopic score with the development of digital skin ulcers in SSc patients through a retrospective analysis. According to the results, the total number of capillaries, the maximum diameter and the ratio between number of giant capillaries and the total number of capillaries correlated with the appearance of ischemic ulcers.

NVC has also been assessed, together with autoantibodies, as a predictor of SSc in a cohort of 586 patients with Raynaud's phenomenon and no definite connective tissue disease. Patients were evaluated for microvascular damage by nailfold capillaroscopy and for SSc-specific autoantibodies by specific assays, in order to identify markers predicting the evolution to definite SSc. Of these patients, 12.6% developed a definite SSc over the years. The results showed that, in patients with Raynaud's phenomenon, and abnormal capillaroscopy with scleroderma pattern together with an SSc-specific autoantibody at baseline, there was a good probability of 79.5% developing definite SSc after up to 9 years of observation.

Very early diagnosis of SSc is an unmet clinical need. To increase the chance of accurately detecting very early SSc patients, experts from the EULAR Scleroderma Trials and Research (EUSTAR) recently identify through a Delphi consensus study a core set of preliminary items considered as important for the very early diagnosis of

SSc. While Raynaud's phenomenon, puffy fingers and antinuclear antibodies were considered by the whole assembly of EUSTAR as "red flags" for the general practitioner leading to the suspicion of very early SSc, NVC was considered, together with anticentromere and antitopoisomerase-I antibodies, as the preferred confirmatory diagnostic tool to diagnose a patient with very early SSc with a high probability. The further validation of these criteria, including NVC, is ongoing in the VEDOSS (Very Early Diagnosis Of Systemic Sclerosis) prospective observational cohort.

More recently, new EULAR/ACR classification criteria for the diagnosis of SSc have been elaborated in order to encompass a broader spectrum of SSc including patients whose disease is in the early stage, as well as those with the limited cutaneous subset. These criteria now include NVC, and the presence of an abnormal nailfold capillary pattern consistent with SSc, defined by enlarged capillaries and/or capillary loss with or without pericapillary haemorrhages at the nailfold, counts for 2 points (9 are required for a diagnosis of SSc). The presence of NVC in these new criteria strengthens the efforts of the clinician to reach an early diagnosis of SSc. Moreover, considering the value of magnified nailfold visualization in the diagnosis and management of SS, these new criteria may encourage acquisition of this skill by physicians caring for SSc patients.

Table 1 – SSc NVC patterns

early pattern	few (fewer than four altered capillaries per millimetre) enlarged/giant capillaries, few capillary haemorrhages, relatively well-preserved capillary distribution, no evident loss of capillaries;
active pattern	frequent (more than six altered capillaries per millimetre) giant capillaries, frequent capillary haemorrhages, moderate loss of capillaries, mild (between four and six altered capillaries per millimetre) disorganization of the capillary architecture, absent or mild ramified capillaries
late pattern	irregular enlargement of the capillaries, few or absent giant capillaries and haemorrhages, severe loss of capillaries with large avascular areas, disorganization of the normal capillary array and ramified/bushy capillaries.

IN-DEPTH DISCUSSION II

Pulmonary hypertension in systemic sclerosis

Pulmonary hypertension (PH) is a fatal disorder characterized by an increase in pulmonary vascular resistance, which leads ultimately to right ventricular failure. The interest in PH due to systemic sclerosis (SSc-PH) has recently increased, as SSc is the connective tissue disease most often associated with PH.

Epidemiology of PH and PAH

SSc-PH prevalence stands about 9% according to a recent meta-analysis, and incidence about 0.61 patient-years. Isolated pulmonary arterial hypertension (PAH) related to obstructive proliferative vasculopathy of the small and medium-sized pulmonary arterial circulation and PH secondary to chronic hypoxemia due to advanced lung disease are the two major causes of precapillary PH in SSc. Pulmonary veno-occlusive disease is also a recognized cause of PH, which is thought to be more common in connective tissue diseases but remains exceptional. In addition, left heart disease and thromboembolic disease may cause, respectively, post capillary/venous, and precapillary PH.

PH and PAH have been associated with significantly high mortality and morbidity rates. One- and three-years survival rates are 78-87% and 47-64% for patients with SSc-PAH. Survival is even worse for those with lung disease-associated SSc-PH (three-year survival 28-39%). Among SSc patients prospectively followed in the EUSTAR cohort, 26% of death was related to PAH. The outcomes of 76 SSc-PAH patients have been recently reported and prognostic factors investigated. In multivariate analyses, pulmonary vascular resistance, stroke volume index, pulmonary capacitance, pulmonary arterial oxygen saturation, estimated glomerular filtration correlated with prognosis. Therefore, this study correlates pulmonary vascular end-points with non-pulmonary conditions that may be of critical importance to explain the specific poor outcomes observed in SSc-PAH.

Definition of PAH

The gold standard for the diagnosis of PH is right heart catheterization (RHC). Precapillary PH is defined at RHC as a mean resting pulmonary artery pressure >25 mmHg in the presence of a pulmonary capillary wedge pressure ≤ 15 mmHg. The importance, when PH is suspected, to systematically proceed with RHC has been emphasized by several reports; indeed, in a series among 206 patients who had a RHC performed for a suspected PH, precapillary PH was confirmed only in 64 patients (31%); 123 patients (60%) had normal hemodynamic measurements, 17 (8%) had PH secondary to left heart disease and 2 (1%) pulmonary veno-occlusive disease.

Early diagnosis

Despite the proven association of PAH and lethality, this complication often remains undetected clinically until frank right heart failure occurs. In general, a substantial delay exists between the presentation of initial symptoms and the diagnosis of PAH. As a result, more than two-thirds of the patients exhibit functional class

(FC) III or IV symptoms at the time of diagnosis. This highlights the need for the early diagnosis of PAH to improve prognosis and to optimize therapy. Hence, screening for PAH in the high-risk scleroderma patient is of paramount importance.

According to the WHO guidelines, baseline and annual Doppler echocardiography is recommended. This practice is intended to identify most cases of PAH. However, the usefulness of ECHO is limited, as it cannot distinguish between the underlying causes of PAH. It may falsely indicate PH when it is actually not present, especially at the upper limits of normal pulmonary artery pressure (PAP in 35–40 mmHg range), and in rare cases, it may fail to detect elevated pulmonary pressure when present. Right heart catheterization (RHC) is therefore necessary for confirmatory diagnosis. The contribution of DLCO as a screening tool in addition to echocardiography has been highlighted: a decreased DLCO <50% identified in a recent series a subset of patients with confirmed PH despite normal sPAP. Increased levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) is also interesting in this context as it has been found as an accurate, reproducible and simple marker of PH.

Exercise echocardiography might also be very helpful to identify a subset of SSc patients with an inappropriate exercise-induced increase in PASP and early signs of right ventricular dysfunction that can relate to very early PAH. This tool is now under development in order to standardize the testing and determination normal values for controls.

Indications of RHC in case of suspected PH

An increase of systolic pulmonary artery pressure or volume of tricuspid regurgitation on echocardiography, reduced DLCO (without significant lung fibrosis), increased NT-proBNP levels, or unexplained dyspnoea have been previously used alone or in combination as indications to refer patients to RHC in case of suspected PAH.

Predictive factors of PH

The marked impact of PAH on the survival of patients suffering from SSc urgently mandates the identification of the subset of patients at highest risk, in order to implement an appropriate follow-up. PH may affect both genders at all ages, highlighting the need for a high index of suspicion and the routine screening of all patients. Although PAH was considered to be a late complication of limited cutaneous SSc, confirmed by reproducible studies, a recent French study showed that the incidence of PAH developing within 5 years after the diagnosis of SSc, was approximately 50% among patients with diffuse cutaneous SSc. Therefore, all patients should be screened for PH immediately after the diagnosis of SSc has been made and very regularly.

Previous retrospective works and some recent prospective ones have highlighted the critical input of pulmonary functional tests to predict the subsequent development of PAH and PH in SSc. In this context DLCO

is of very high value it must be used as a warning tool and patients with significant decrease of DLCO, notably in the absence of significant lung fibrosis, should be very scrupulously regularly followed for the risk of PAH. The combination of DLCO and increased NT-proBNP levels has been shown to highly predictive of the occurrence of PAH. Several attempts are ongoing to build predictive risk scores. Genetic might also be a promising approach to identify patients at risk to develop PAH, since several gene polymorphisms have been reported to be associated with the risk of SSc associated PAH.

Outcome measures of PH

SSc-PH patients require repeated assessments of either disease progression and/or treatment efficacy. Dyspnoea, functional classification, exercise capacity, hemodynamic changes and cardiac function are considered to be important for PH evaluation and prognosis. However, these outcome measures, especially the 6 min walk test, are only partially validated in PAH associated with SSc. The development of new tools, such as Tissular Doppler echocardiography, cardiac magnetic resonance imaging or new biomarkers might improve the evaluation of PH and better define the prognosis and response to therapy.

Treatment

In addition to the supportive care (oxygen, diuretics, anticoagulants), experts from EUSTAR recommended to consider the use of endothelin receptor antagonists, PDE5 inhibitors and prostanoids to improve exercise capacity, functional class and some hemodynamic measures in PH associated with SSc. Since disease worsening is inevitable for the majority of patients receiving monotherapy, there is increasing interest in the use of treatment combinations. A recent event-driven randomized controlled trial has shown that combination therapy with agents that target different pathways may potentially increase the overall therapeutic effect on the mechanisms of this disease and provide additional clinical benefits. Early treatment initiation and optimization following early detection could be the key to reducing the mortality associated with PH in SSc.

IN-DEPTH DISCUSSION III

Articular involvement in systemic sclerosis

While tethering of the skin is the clinical hallmark of systemic sclerosis (SSc), many patients develop musculoskeletal symptoms, during the course of their illness. Articular involvement contributes to disability and impaired quality of life in SSc.

CLINICAL PRESENTATIONS

Joint involvement eventually affects 46-97% of patients with SSc. The systematic cross-sectional examination of the EUSTAR registry identified clinical synovitis, defined by tender and swollen joints and tendon friction rubs (defined by a leathery, rubbing, “squeaking” sensation detected as the tendon is moved actively or passively) in 16 % (1191/7286) and 11% (802/7286) of SSc patients, respectively. Joint involvement may be an initial manifestation that precedes the onset of Raynaud’s phenomenon or arise concomitantly and therefore might be considered as an early indicator of SSc.

1/ Joint involvement

Generalized arthralgias with slight pain and stiffness are the usual presentations of articular involvement; however, true joint inflammation may occur and be a source of initial diagnostic confusion. The onset may be acute or insidious and oligoarticular or polyarticular in pattern. Virtually, all joints may be affected, although the fingers (in particular the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints), wrists and ankles predominate. As the disease progresses, there is tethering and contracture of the underlying joints with impairment of movement and function.

2/ Tendon involvement

Tendon abnormalities are described as “leathery crepitus” on palpation of the knees, wrists, fingers and ankles, related to fibrinous deposits on the surface of tendon sheaths and overlying fascia. In the forearm the source of this rub is usually the tendons of the flexor or extensor muscles immediately proximal to the wrist. Median nerve compression with carpal tunnel syndrome may occur, presumably from changes in the tendon sheaths beneath the transverse carpal ligament.

LABORATORY FINDINGS

Rheumatoid factor positivity occurs in up to 30% of SSc patients. This test seems non-specific and does not distinguish SSc patients with musculoskeletal manifestations from those not so affected. Rheumatoid factor may also be seen in patients with SSc associated secondary Sjögren’s syndrome. The search for anti-CCP antibodies might be of great help in the identification of the infrequent cases of true SSc-rheumatoid arthritis overlap. Analysis of the synovial fluid generally reveals normal or modestly increased leukocyte concentrations of less than 2000 cells/mm³ and a predominantly mononuclear infiltrate.

ARTICULAR INVOLVEMENT AS A CORRELATE OF PROGNOSIS AND DIAGNOSIS OF SSc

In the EUSTAR registry, patients with synovitis and early disease were more likely to experience diffuse cutaneous thickening. However, the likelihood of severe vascular (pulmonary hypertension) and muscular (muscle weakness) involvement was higher in patients with synovitis, regardless of their cutaneous subset or their disease duration. One study also identified an association between synovitis and elevated acute phase reactants, suggesting that joint involvement might be associated with systemic inflammation in SSc. Tendon involvement is more prevalent in patients with the diffuse cutaneous subset and early disease and tendon friction rubs is associated with poor outcomes including decreased survival.

Two recent prospective cohort studies including patients from the EUSTAR database have identified joint synovitis as a predictor of disease progression. The first study included 1,301 SSc patients with disease duration ≤ 3 years at inclusion and with a follow-up ≥ 2 years (mean follow-up: 4.5 ± 2.2 years). Joint synovitis, detected by clinical examination, was independently predictive of the worsening of the modified Rodnan skin score ($\geq 30\%$ and ≥ 5 points) and of the further occurrence of new ischemic digital ulcers and decreased left ventricular ejection fraction. The second study was performed on 637 SSc patients with the diffuse cutaneous subset. Joint synovitis was also identified in univariate and multivariate analysis as a predictor for progressive skin fibrosis. Using a second validation cohort of 188 dcSSc patients, joint synovitis were confirmed as independent predictors of progressive skin fibrosis within 1 year. Taken together, the results of these two studies support that synovitis, an easily detected clinical marker may be useful for the risk stratification of SSc patients.

The recent prospective analysis of the EUSTAR database has also confirmed that tenosynovitis was an independent predictor of skin progression and of the further occurrence of scleroderma renal crisis.

RADIOLOGIC FEATURES: STRUCTURAL OSTEOARTICULAR LESIONS

Articular lesions, from juxta-articular osteoporosis and joint space narrowing to frank erosions, have been reported throughout the MCP, PIP and DIP joints, as well as the wrist (figure 1). Patterns of SSc arthropathy range from that resembling erosive osteoarthritis or psoriatic arthritis with relative sparing of MCP joints to changes reminiscent of rheumatoid arthritis. The frequency of hand radiographic erosions is between 5% and 40%. Joint space narrowing prevalence on X-Ray is about 30%, with a predominant involvement of DIP joints. The detection of pencil-in-cup deformity in hands and feet has been reported. These articular features may be associated with non-articular abnormalities, in particular skin atrophy, subcutaneous calcinosis and digital tuft resorption, which are among the most distinctive radiographic findings in SSc.

In a prospective cohort involving 120 SSc patients, erosive arthritis defined as the occurrence of both erosions and joint space narrowing, was found in 18% of SSc patients. The five-year longitudinal follow-up of these

patients, with a systematic examination of dual time-point X-Rays, showed a total radiographic progression of erosive arthritis in 24 (23%) SSc patients. The presence of erosive arthritis was not associated with any SSc characteristics or auto-antibodies. This lack of any predictive factor for erosive arthritis might be related to the multifactorial aspects of SSc arthropathy. The possibility of erosive osteoarthritis should be considered; in our view, some patterns of erosive arthropathy can be directly related to SSc, however DIP involvement suggests coincident OA. The recent development of power Doppler ultrasonography, which allows the assessment of synovial vascularity, and magnetic resonance imaging as diagnostic tools and outcome criteria in rheumatoid arthritis has led to a substantial improvement in disease evaluation. The higher sensitivity of these non-invasive techniques to detect joint/tendon involvements has been demonstrated and several studies evaluating their input are ongoing.

TREATMENT

For the most part, arthralgias, but also tendonitis, will respond to simple non-steroidal anti-inflammatory drug treatment. Caution should be exercised, however, with this class of drugs because of the enhanced risk of gastro-oesophageal abnormalities or bleeding and impaired renal function in this group of patients. Low dose corticosteroids (<10 mg/day) may also be used, although the risk of renal crisis should be carefully considered (especially in diffuse SSc patient within the first 5 years of SSc onset and in case of positive anti-RNA pol III antibodies). Methotrexate may be used for the treatment of inflammatory arthritis and sub-cutaneous route may improve absorption. Other immunosuppressive drugs may be used, such as azathioprine, but cyclophosphamide did not show beneficial effects on joints in the secondary analyses of the Scleroderma lung Study. A pilot study suggested some interest in very selected severe and refractory SSc-arthritis cases of intravenous immunoglobulins therapy.

Biologics have been the starting point of a new era in the treatment of inflammatory rheumatic conditions. The efficacy of TNF α inhibitors on inflammatory joint symptoms has been suggested in a preliminary study, performed on 18 SSc patients treated with etanercept. However, no further trial has been performed probably because of the risk of exacerbation of fibrosing alveolitis, reported both in SSc and rheumatoid patients. Rituximab, a chimeric monoclonal antibody against the protein CD20 that demonstrated efficacy in RA, might also be potentially beneficial for the treatment of SSc arthritis. However, no study has yet assessed this drug for this specific indication. The EUSTAR group collected observations that revealed a tendency toward articular improvement in cases of polyarthritis under tocilizumab and abatacept during refractory SSc. Further randomized controlled trials are now expected to confirm these promising results.

The current literature on rehabilitation techniques in SSc consists of studies evaluating the effectiveness of paraffin wax treatment, hand and face stretching exercises connective tissue massage and joint manipulation, splints, aerobic exercise and resistance training. The data seem promising, except for splints, for the

improvement in joint motion and hand function. However, larger randomized controlled studies are needed to fully determine the effectiveness of rehabilitation techniques for persons with SSc.

Surgery of the hand for SSc is used but the goals of surgery are limited. They include pain relief, repositioning the digits, providing a functional position of fusion, and in some cases modest mobilization through resection arthroplasty to marginally improve finger function for patients with marked pre-existing limitations. Surgery may also be required in the very rare cases of tendon rupture. In the case of carpal tunnel syndrome, corticosteroids injected under the retinaculum are frequently efficient, but surgical release may be needed in symptomatic and refractory patients. If surgery is contemplated then local or regional anaesthesia is preferred for patients, particularly in patients who have ongoing cardiac or pulmonary manifestations of SSc.

CONCLUSION AND PERSPECTIVES

Although the understanding of osteoarticular pathogenesis has significantly increased in the last few years, optimal treatments of inflammatory joint disease remain to be determined and appear as a major challenge for improving SSc morbidity and patients' quality of life. To that end, the study and validation of outcomes measures including new imaging techniques in this field must be put urgently on the research agenda of the SSc community. Thereafter, one may have the chance to perform rigorous randomized controlled trial assessing the potential input of the many relevant available and upcoming drugs and therefore offering some hope in a disease that remains devastating.

Polymyositis, dermatomyositis

Inflammatory diseases of muscle and other myopathies

Lorenzo Cavagna, Francesco Locatelli, Andrea Doria

A previous version was co-authored by Robert G. Cooper, Andrea Doria, Luca Iaccarino

LEARNING OBJECTIVES

- ➔ Know possible pathogenic mechanisms in inflammatory myopathies.
- ➔ Make an accurate diagnosis of idiopathic inflammatory myopathy.
 - Distinguish between inflammatory and non-inflammatory myopathies.
 - Describe cutaneous specific features of dermatomyositis.
 - Describe other extramuscular features of idiopathic inflammatory myopathies.
- ➔ Describe myositis-specific and myositis-associated autoantibodies and their associated clinical phenotypes.
- ➔ Use clinimetric measures for muscular and extra muscular features.
- ➔ Prescribe both pharmacological and non-pharmacological treatments.

1 Introduction

Idiopathic inflammatory myopathies (IIMs) are a group of autoimmune, rare and heterogeneous muscle disorders characterized by the occurrence of proximal and symmetrical muscle weakness, which can result in impaired endurance and disability. Extra-muscular involvement and the overlap with other well-defined connective tissue diseases (CTDs) (eg Sjögren's syndrome, systemic sclerosis, mixed connective tissue disease, systemic lupus erythematosus or rheumatoid arthritis) are not uncommon in IIMs. IIMs have traditionally been subclassified into three main types: polymyositis (PM), dermatomyositis (DM) and inclusion body myositis (IBM) (Bohan and Peter, 1975). A classification of IIMs according to the presence of myositis-specific and myositis-associated autoantibodies (MSAs/MAAs) has also been proposed, since most MSAs, such as the antisynthetases (Cavagna et al, 2015*), and some MAAs, are associated with distinctive and characteristic clinical phenotypes (Trojanov et al, 2005*). In addition, different subtypes have been identified (necrotising myositis, chronic granulomatous myositis associated with sarcoidosis, orbital myositis, focal myositis and eosinophilic myositis) but they will be not treated in this course.

2 Epidemiology

IIMs are rare diseases, but data about prevalence and incidence are largely inhomogeneous. The variability is due to different methodologies used for patients' inclusion, genetic background and/or environmental factors exposure.

PM/DM prevalence ranges from 2.9 to 34 cases/100.000 inhabitants, with an annual incidence of 2–11 cases/1.000.000 inhabitants, (Svensson et al, 2017). The peak incidence is at the age of 50–60 years, but the onset is possible at any age. The female to male ratio is about 2:1. Juvenile-PM is much rarer than juvenile-DM. Interestingly, PM/DM distribution seems to have a latitudinal gradient, with DM occurring more frequently at latitudes closer to the equator, and PM at northern latitudes, potentially linked to the different UV-light irradiation exposure in these areas. The estimated prevalence of IBM is 3.3/100 000 (Molberg et al, 2016), the estimated annual incidence is 1–2/1.000.000 adults. IBM is more common in males. Mean age at onset is slightly higher in IBM than in PM/DM, and it rarely occurs before the age of 50. It should be noted that both sporadic- and hereditary- forms of IBM have been described.

3 Aetiopathogenesis

The aetiopathogenesis of IIMS is complex and not completely understood, involving both genetic and environmental factors. The interaction between these factors is crucial for the establishment of the autoimmune reaction leading to the occurrence of different manifestations of IIMs.

3.1 Genetic factors

IIMs susceptibility is closely associated with human leucocyte antigen (HLA) genes, in particular HLA class II alleles. In Caucasians, the strongest association is with HLA-DRB1*0301 and DQA1*0501, whereas in Asians it is with HLA-B7, with DQA1*01 acting as a protective factor. An even stronger association has been found between some subsets of myositis and specific autoantibody profiles (anti-Jo-1, HLA-DRB1*0301, DQA1*0501; anti-Mi-2, DRB1*07, DQA*0201). IBM has been associated with HLA-DRB1*0301, DRB1*0101, DRB1*1301, DQB1*0201 and DRw52. Patients with IBM and both DRB1*0101 and DRB1*0301 genes have an earlier onset and a rapid disease progression compared to those without this 'double-dose' of DRB1 genes, clearly suggesting the importance of gene–gene interaction in determining disease phenotype and severity. Recently, two variants of sequestosome 1 (SQSTM1) and valosin-containing protein (VCP) genes, the SQSTM1 p.G194R and the VCP p.R159C, have been found significantly overrepresented in sporadic IBM with respect to controls. These genes are also involved in the pathogenesis of some neurodegenerative disorders, thus a common nature between sporadic IBM and conditions such as amyotrophic lateral sclerosis and fronto temporal dementia is possible (Gang Q et al, 2016). Data on hereditary-IBM are scant, but different genetic transmissions and probably different genetic defects are possibly involved.

The above mentioned genetic associations support the role of T-cell driven immune response in IIMs pathogenesis, as the only known function of major-histocompatibility-complex (MHC) class II molecules is to present antigens to antigen-specific T-cell receptors.

Also non-HLA genes, such as those for proinflammatory cytokines (-308TNFA genotype), have been linked to IIMs. The -308TNFA gene is localised in a conserved haplotype (the ancestral haplotype) on chromosome 6, including also HLA-DR3 and other genes potentially relevant for the development of chronic inflammatory diseases. Whether the association between myositis and the HLA-DR3 gene or the tumour necrosis factor (TNF) gene depends on an association with a single gene or an extended haplotype is unclear. There are also reports of associations with a polymorphism in the interleukin-1 receptor antagonist (IL-1Ra) gene in juvenile-DM, where the IL-1RN A1 allele carries an increased risk for juvenile-DM.

Despite these evidences, it is clear that the genetic background in IIMs pathogenesis is complex and largely still to be defined. Furthermore, it is possible that environmental factors could interact with genetic

predisposition leading to IIMs occurrence. A single and relatively small study has tantalisingly suggested that smoking and HLA-DRB1*0301 (or DR3) may predispose to expression of the anti-Jo-1 antibody.

3.2 Environmental factors

3.2.1 Infections

Acute and self-limiting forms of myositis have been reported with Coxsackie, echo and influenza virus infections, in particular in children, but their role in chronic myositis is uncertain. Both clinical and histopathological features resembling PM have been seen in patients with retroviral infections, such as human T-cell leukaemia/lymphoma virus and human immunodeficiency virus. Also, *tripanozoma cruzi* infection has been associated with myositis. However, in the majority of patients with myositis, there is no proof of viral infection in involved muscles.

3.2.2 Exposure to UV light and vitamin D deficiency

The above-mentioned different latitudinal gradient of prevalence between PM and DM seems to indicate that UV light exposure may predispose to DM development. This link seems to be particularly evident in patients positive for anti-Mi-2 autoantibodies. The association between exposure to UV light and this specific myositis subset suggests that UV light may be an exogenous modifier that can differentially influence IIM clinical phenotype features, although with mechanisms that are still not defined.

Similarly to other CTDs, also vitamin D deficiency has been linked to IIMs (Azali et al, 2013), but the pathogenetic influence of this deficiency is still unclear.

3.2.3 Drugs

Among the different environmental factors linked to IIMs, the impact of drugs is not univocal. Several drugs may induce myopathies with muscle weakness and increased serum levels of creatine kinase (CK), that may resemble IIMs but that do not always belong to the IIMs spectrum. The most common drug-induced myopathy is caused by statins, but also other lipid-lowering agents (fibrates and nicotinic acid) may induce a myopathy. While statin use is very common, statin-induced myopathy is extremely rare. Predominant clinical features in statin-induced myopathy include generalised muscle pains and cramps and, sometimes, severe rhabdomyolysis, with a risk of renal failure due to the ensuing myoglobinuria. Muscle biopsy samples in statin-induced myopathy are usually normal without inflammatory cell infiltrates, though in more severe cases myonecrosis of fibres may occur (necrotizing myopathy), with or without inflammatory cell infiltration. The prognosis is usually favourable, with spontaneous recovery commonly occurring when the drug is stopped, though recent case series have reported that statin-induced myopathy may not regress after drug cessation. In persistent cases, the use of immunosuppressants such as methotrexate, or high dose intravenous immunoglobulins (IVIg) may induce disease remission (Trojanov et al, 2017).

However, if muscle symptoms persist after a lipid-lowering drug has been discontinued, the possibility of another underlying problem, such as a metabolic myopathy unmasked by the drug should be strongly considered.

The mechanism by which statins cause myopathy remains unknown, but may be associated with the fact that these drugs are 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (HMGCR) inhibitors, and such inhibition may interfere with energy production. This may lead to damage of muscle fibres and the overexpression of HMGCR by regenerating muscle fibres. The damage is mediated in some patients by anti-HMGCR antibodies, strongly associated with the HLA-DRB1*1101 gene. This autoimmune profile, reported also in non-statin users with myositis, together with clinical and therapeutic overlaps with PM/DM, could strengthen the hypothesis that some subsets of statins-related myopathy could be considered as IIMs (Albayda et al, 2014).

Other drugs that may rarely induce myopathies are cimetidine, (hydroxy)chloroquine, amiodarone and colchicine. In general, drug-induced myopathies can be distinguished from inflammatory myopathies by the history of drug usage, by an absence of inflammatory changes in muscle biopsy specimens and by the clinical improvements after drug withdrawal. Glucocorticoids may induce a myopathy, exclusively characterized by the histological occurrence of a non-specific atrophy of type II muscle fibres. In patients with IIMs on glucocorticoids treatment, the diagnosis of glucocorticoid-induced myopathy may only be established if muscle strength improves when the glucocorticoid dosage is reduced. Some cases of anti-TNF-alpha-induced myositis have been described in RA patients. By considering the frequent anti-Jo1 positivity since disease onset in these cases and recent advances on the clinical spectrum time-course in anti-Jo1 positive patients (*Cavagna et al, 2015), it is possible to speculate that myositis occurrence may be more likely related to the natural history of the disease rather than to the anti-TNF-alpha treatment. Alcohol and cocaine may rarely induce an acute rhabdomyolysis, but alcohol more commonly induces a chronic myopathy. Typically, although not specific, histopathological findings in alcohol-induced myopathy include an accumulation of fat in muscle fibres without inflammation.

4 Pathogenesis

4.1 Immune mechanisms

Both adaptive and innate immunity may play a role in the development of muscle inflammation in IIMs, in line with the occurrence of T-cells infiltrates in muscle tissue, HLA-DR associations, presence of myositis-specific and associated autoantibodies, hyperactivation of interferon (IFN) type I signature and pattern-recognition receptor-dependent pathways. Most targeted antigens in IIMs are ubiquitously expressed. Possibly, immature muscle precursors enhance local auto inflammation in muscles, linking innate and adaptive immune responses (Casciola-Rosen et al, 2005*; Tournadre and Miossec, 2013). Besides immune mechanisms, some non-immune mechanisms are emerging, which are likely to have a role in muscle damage (Vitadello et al, 2010).

4.1.1 Adaptive immunity

4.1.1.1 T-cells

T lymphocytes and macrophages dominate the inflammatory infiltrate in PM, often with a relatively high proportion of CD8 T-cells compared with CD4 T-cells in the endomysial infiltrates. In some cases, these infiltrates surround and seem to invade closer fibres with otherwise normal histology. In contrast, in DM infiltrating CD4 T-cells with a perivascular localisation, mainly in the perimysium, are predominant with respect to CD8 T-cells. Despite their widespread localisation, the precise role of T-cells in the pathogenesis of IIMs has not been clarified yet. T-cells display an activated phenotype, yet the driving antigen for T-cell activation has not been identified. It is interesting to note that restricted T-cell receptor (TCR) expression has been characterised in muscle tissue, suggesting homing or local proliferation of T-cells. Autoreactive T-cells in muscle tissue normally act both as antigen-presenting cells (APCs), (CD4), which can support B-cell proliferation and differentiation, and as cytotoxic effectors against muscle fibres overexpressing MHC I molecules (CD8). A new subset of T-cells, the CD28 null T lymphocytes, arising from a prolonged stimulation of T-cells, leading to CD28 exhaustion, is widely expressed in inflammatory infiltrates and in the peripheral blood of patients with IIMs. These cells are resistant to apoptosis and to immunosuppressive therapies and may persist in muscles for a long time. CD28 null T-cells have acquired cytotoxic properties and can secrete large amounts of inflammatory cytokines and cytotoxic molecules—for example, granzymes and perforins (Malström et al, 2012). By considering that regulatory T-cells are reduced and/or functionally deficient, proinflammatory T-cells—for example, Th17, increase in inflammatory infiltrates. T-cells seem to be target of a proinflammatory shifting of the immune balance in IIMs. IL-17 can then trigger the release of a number of proinflammatory Th1 cytokines—for example, IL-2, IL-1, IL-6 and IL-15—, and can induce an increase in MHC I expression on muscle fibres.

4.1.1.2 B-cells and plasma cells

B-cells infiltrates are less common in IIMs, more often with a perivascular localisation in DM, particularly in the subtype associated with calcinosis in children. However, microarray studies have shown the presence of Ig transcripts, dendritic cell (DC) transcripts and IFN type I (α and β) transcripts in muscle fibres of patients with IIM (Greenberg, 2007*), suggesting that plasma cells and DCs have a role in the development of muscle inflammation. Indeed, plasma cells (CD138+) have been found to infiltrate muscle fibres in PM to a greater extent than immature activated B-cells, and molecular characterisation of Ig variable region sequences showed isotype switching and somatic hypermutation in the presence of clonal expansion, suggesting that a local antigen-driven maturation of B-cells in inflamed muscle may occur. Effectiveness of anti-CD20 treatment in IIMs suggests that activated immature B-cells are also involved in the pathogenesis of muscle damage, but the driving antigen still remains unclear.

4.1.1.3 Autoantigens and autoantibodies

Autoantibody specificities and their usefulness in the clinical evaluation of IIMs are discussed in detail in section 6.5. From the pathogenetic point of view, it is possible that MSAs play a pathogenetic role, since their serum levels correlate with disease activity. Probably, autoantibody-mediated damage in IIMs results from well-characterised mechanisms—for example, antibody-dependent cellular cytotoxicity or complement fixation. The question is how ubiquitously expressed intracellular autoantigens drive damage to a particular muscle or specific disease phenotypes—eg the antisynthetase syndrome (ASSD).

The increased tissue- and muscle-specific antigen immunogenicity in IIMs, thereby shaping a dedicated immune response, has been linked to two different mechanisms: first, the increased expression of antigens in muscle tissue and second, the acquisition of adjuvant activity by autoantigens (Suber et al, 2008*). Regarding the first mechanism, it has been shown that myositis-specific autoantigens are overexpressed in inflamed muscle in IIMs, particularly by regenerating muscle cells, which can therefore emerge as preferred targets of the immune response. Moreover, most antigenic autoantigens have proinflammatory properties and can themselves exert a chemoattractant effect on immune and inflammatory cells; in this regard, it is interesting to note that the histidyl-tRNA synthetase (Jo-1) can attract leucocytes through chemokine receptor 5, while this does not apply to other non-immunogenic synthetases (e.g., aspartyl-tRNA synthetase). Regarding the second mechanism, self-antigens may become more immunogenic, as they are released in the extracellular space and undergo post apoptotic modifications. It is noteworthy that a common feature among myositis-specific antigens is their susceptibility to granzyme B-mediated cleavage, which is secreted by cytotoxic lymphocytes and CD28 null T-cells, thereby generating new antigen conformations and/or neo-epitopes that can trigger the positive selection of autoreactive T and B-cell clones. Interestingly, the initiating tissue in some cases may be far from the muscle itself. For example, a new conformation of the histidyl tRNA synthetase (e.g. the Jo-1) is found in the lungs of ASSD with interstitial lung disease (ILD) (Levine SM et al, 2007). Additionally, T-cells infiltrating muscle tissue were shown to express the same TCR as T-cells coming from bronchoalveolar lavage of such patients, showing a large expansion of the variable region TCR-V3b. This suggests that the triggering antigen of the primary immune response is localised in the lung, at least in anti-Jo1 positive patients. Finally, association of most myositis autoantigens with nucleic acids makes them likely to stimulate the IFN type I secretion pathways, which in turn can increase antigen availability and propagation of the immune response, as discussed later in this section.

4.1.1.4 Dendritic cells: DCs can link innate immunity with adaptive immunity; they function as sentinels of the immune system exposing a variety of pattern-recognition receptors (e.g., TLRs and C-type lectin receptors (CRLs)) by which they capture antigens in the periphery and then become activated mature professional APCs capable of priming and activating antigen-specific T-cells. Myeloid DCs mostly function as APCs, whereas plasmacytoid DCs are major producers of type I IFN. Both DC types have been found in inflammatory muscular

infiltrates of patients with IIMs (PM, DM, juvenile-DM and, to a lesser extent, IBM) at both immature (CD1a+) and mature stages (CD83 and DC-LAMP) (Greenberg, 2005). The presence of their ligand CCL20 together with the lack of the C-C motif chemokines CCL19 and CCL21 suggests that maturation of DCs can occur locally, leading to an abnormal accumulation of activated DCs in muscle.

4.1.2 Innate immunity

4.1.2.1 Interferon signature

Type I IFN is known to foster autoimmunity in several autoimmune systemic disorders including systemic lupus erythematosus (SLE). Growing evidence suggests that activation of IFN α/β pathways can also sustain autoimmunity in IIMs through enhancement of innate responses, induction of maturation of B-cells and DCs and stimulation of cytokine production by bystander cells (Greenberg, 2005). Patients with IIM show an increased expression of IFN-inducible genes in muscles and blood. Plasmacytoid DCs are probably the major local producers of IFN I as they can be stimulated by immune complexes containing RNA, similar to the process in SLE. Interestingly, recent data have shown that immature muscle precursors also act as a local source of IFN β in inflamed muscle. Recently, a high IFN score, potential trigger for type I IFN pathway activation in peripheral blood, has been associated with DM, IBM and with autoantibodies against RNA-binding proteins, such as the anti-Jo1 (Ekholm L et al, 2016).

4.1.2.2 Pattern-recognition receptor activation

Pattern-recognition receptors (Toll-like receptors, TLRs, and C-Type Lectin Receptors, CLRs) are usually activated by sensing microbial pathogen-associated molecular patterns, or they can be activated by endogenous ligands with concurrent nucleic acid-associated autoantigen recognition, leading to dysregulated activation of the immune cells on which they are expressed—for example, DCs. Interestingly, TLR3 and TLR7 are overexpressed in inflamed muscle tissue during IIM, whereas they are absent in non-inflammatory myopathies or healthy muscle (Cappelletti et al, 2011). Additionally, immature muscle precursors express high levels of TLR, the activation of which leads to increased IFN β release, which in turn can stimulate HLA-I expression on muscle cells. Upon TLR stimulation, immature muscle precursors can themselves release proinflammatory cytokines—for example, IL-6, or chemokines such as CCL20, which contribute to further T-cell recruitment and differentiation towards a proinflammatory Th17.

4.1.2.3 Cytokines

A high number of cytokines and chemokines has been detected in muscle tissue from patients with myositis and may play a role in the pathogenesis of myositis. The most frequently reported cytokines in all three traditional subsets of IIM are the proinflammatory cytokines IL-1 α , IL-1 β and TNF α . Recent clues have linked TNF α overexpression with muscle wasting. Indeed, cytokine expression on muscle specimens from patients with

myositis showed that myogenic miRNAs were reduced in comparison with healthy controls. Moreover, lower levels of myogenic miRNAs were coupled with higher levels of proinflammatory cytokines, including TNF α . Thus, it is suggested that TNF α might inhibit the differentiation of myoblasts into myocytes in the inflamed muscle (Georgantas et al, 2014). Recently, another proinflammatory molecule, the DNA-binding high-mobility group box 1 (HMGB1), was demonstrated with an extra nuclear and extracellular pattern in muscle tissue of patients with PM and DM. HMGB1 is ubiquitous and found in the nuclei of all cell types, but can be released from monocytes and macrophages on stimulation. Moreover, HMGB1 can be released from cells that undergo necrosis and is thus characterised as alarming. HMGB1 can induce production of other proinflammatory cytokines such as IL-1 and TNF. Thus, HMGB1 may be an endogenous factor that can induce and perpetuate inflammation by its release from injured cells, such as degenerating or necrotic muscle fibres or by active release from macrophages. Cytokines may induce upregulation of MHC class I and II molecules on muscle fibres but may also have a direct effect on muscle fibre function, as shown for TNF α and for HMGB1. IL-15 may induce the inflammatory infiltration of macrophages in PM patients through the NF- κ B pathway and MMP-9 expression level (Yan W et al, 2016). Furthermore, serum levels of IL-35 could act as a IIMs disease activity marker and as a risk factor for the occurrence of oesophageal involvement. Even if IL-35 may participate in the pathophysiological processes of IIMs, involved mechanisms are not known (Yin L et al, 2016). The importance of different cytokines and chemokines in the disease mechanisms of myositis is still uncertain but they constitute potential targets for development of new treatments.

4.2 Non-immune mechanisms

Recent studies highlighted the role of non-immune-mediated muscle damage in IIMs. The major mechanisms involved are endoplasmic reticulum (ER) stress, hypoxia and autophagy, which are thought to be tightly linked. Among these, the best characterised is ER stress. ER stress is generated after accumulation of misfolded or unfolded cellular proteins within the organelle. It can result in both the unfolded protein response or in the ER overload response, which are not mutually exclusive and lead to exaggerated gene expression of proinflammatory cytokines, adhesion molecules, HLA-I molecules and further fuelling of the ER feedback loop (Vitadello et al, 2010; Ghirardello et al, 2011). The overexpression of class MHC I molecules in muscle cells causes large amounts of MHC transcripts to accumulate within the ER, thereby enhancing a stress response which results in activation of the NF- κ B pathway via the ER, further ER flooding with induced gene transcripts and, eventually, cell death and autoantigen release in the extracellular space. Moreover, the sarcoplasmic reticulum is a specialised form of ER in muscle cells, which is responsible for calcium homeostasis; hence, perturbations of sarcoplasmic reticulum function due to overload may cause muscle cell disruption and further antigen release, which, in turn, can bind autoantibodies and activate IFN type I secretion, leading to a proinflammatory feedback loop.

4.3 A unifying hypothesis

How innate and adaptive immune responses together can generate and perpetuate inflammation in muscle is still a matter of debate; however, a unifying hypothesis has been proposed converging on the role of immature muscle precursors.

Immature muscle precursors are juvenile regenerating muscle fibres awakening in injured muscles. Previous findings have shown that regenerating muscle fibres express high levels of myositis-specific autoantigens, yet antigens are scarce on mature myotubes. Furthermore, mechanisms underlying activation and differentiation of myoblasts along the myogenic lineage are likely to resemble postnatal myogenesis. Thus, it is probable that on a predisposed genetic background any muscle damage induces repair pathways, during which myositis autoantigen expression and release are increased. Since autoantigens are mainly composed of protein–nucleic acid complexes they can induce TLR stimulation on their own or after ligation of cognate autoantibodies, thereby leading to type I IFN production, IL-6 and CCL20 release, DC stimulation and a self-perpetuating feedback loop resulting in lymphocyte activation and autoantibody production. These mechanisms are also likely to play a role in paraneoplastic IIM. Antigenic similarity with regenerating myoblasts and even expression of myositis autoantigens has been proved in cancer cells, which may result in cross-reactivity with muscle tissue (Casciola-Rosen et al, 2005*). Interestingly, muscle specimens of patients with cancer but without IIM showed histopathological features similar to those seen in IIM, with signs of muscle damage and regeneration. Possibly, inflammation evoked by the malignancy may injure muscle tissue, thus allowing antigen availability for the anti-tumour immune response, which would also affect muscle tissue (Ghirardello et al, 2011). Finally, damaged regenerating muscle fibres increase surface expression of HLA-I, which is also fostered by IFN β within an inflammatory microenvironment and as such become more susceptible to T-cell-mediated cytotoxicity and to ER stress responses, causing further autoantigen release. Thus, immature muscle precursors may serve as both targets and culprits of the autoimmune response, leading to muscle inflammation (Tournadre and Miossec, 2013).

5 Clinical features

5.1 Polymyositis and dermatomyositis

5.1.1 Muscle involvement

Muscle weakness with impaired muscle endurance and excessive muscle fatigue are common symptoms of PM/DM. The weakness is most pronounced in proximal muscle groups, usually with subacute or insidious onset and symmetrical distribution. Patients typically have difficulty in rising from chairs, and walking uphill or upstairs. In untreated cases muscle weakness progresses slowly, leading in most severe cases to wheelchair dependence. Patients may have difficulty in swallowing and eating owing to impaired contractility of the palatal and

pharyngeal muscles. This condition may put the patients at high risk of aspiration pneumonia, and so the airway may need temporary protection using tube-assisted feeding. In some patients, palatal and pharyngeal muscle weakness may also cause voice alterations. Breathing difficulties due to weakness of the diaphragm and/or the thoracic muscles are possible but they occur rarely. In severe cases, temporary assistance with mechanical ventilation is required.

5.1.2 Skin involvement

Cutaneous manifestations of DM are frequently pathognomonic. They may precede the muscle symptoms by months or years. Patients who have hallmark cutaneous manifestations of classic DM occurring for ≥ 6 months in the absence of clinical or laboratory evidence of myositis are classified as having a clinically amyopathic DM. This form of myositis may also be associated with malignancies, as is the case of classic DM. Other forms of DM are hypomyopathic DM, in which cutaneous manifestations of DM are associated with subclinical evidence of myositis; post-myopathic DM, in which patients with previous classic DM recover from myositis but the skin rashes remain active; and DM sine dermatitis, in which no rash is detected but histological features of the muscular biopsy sample are indicative of DM.

Gottron's papules (or plaques), which are about 1 mm thick, violaceous, pink or dusky red papules located over the dorsal side of metacarpal or interphalangeal joints (figure 1), are considered to be pathognomonic of DM. These papules may also occur over the extensor side of the wrist, elbow, knee or other joints. Macules located in the extensor site of joints are also described and are called 'Gottron's sign'. Another characteristic skin rash in DM is the heliotrope rash, a periorbital violaceous erythema of one or both eyelids often with oedema (figures 2 and 3). Red or violaceous erythemas may also be located over the shoulders, neck and chest (shawl sign, V-sign) (figures 4 and 5) or over the hips (holster sign) (figure 6). Other characteristic skin lesions are the periungual nailfold telangiectasias and/or cuticular haemorrhage, infarct and/or dystrophy (figure 7). Mechanic's hands consist of hyperkeratosis and scaling and fissuring of the skin, particularly of the radial side of the index finger; and it is more commonly associated with anti-Jo-1 autoantibodies as part of the ASSD (figure 8). A severe generalised erythema, or erythroderma (figure 9), occasionally with vesiculobullous lesions or ulcers (figure 10), may rarely occur. Other uncommon skin lesions are panniculitis, livedo reticularis (figure 11), non-scarring alopecia and vesiculobullous lesions. Cutaneous calcinosis, sometimes severe and painful, is occasionally seen in adults, being more common in juvenile-DM, (figure 12). Calcinosis predominantly occurs at sites that are subject to pressure or friction, such as the dorsal side of the elbows, it may be localised to the skin, subcutaneous fat, fascia and muscle, and it can be clearly visible in skin or muscle on X-ray/MRI examination. A DM skin rash may be precipitated or aggravated by UV light exposure. Patients with DM skin manifestations may complain of itching and pain. Histopathological skin features are non-specific and mostly overlap with those seen in patients with SLE. Thus, skin biopsy is an unhelpful diagnostic tool for DM.

Figure 1 Gottron's changes are defined as erythematous to violaceous papules and plaques (Gottron's papules), or macules (Gottron's sign), over extensor surfaces of joints, generally distributed symmetrically. The figure shows the most common distribution over the metacarpophalangeal and interphalangeal joints (A), occasionally with a hint of ulceration in a juvenile patient (B). An interarticular rash may occur at the same time in some patients (C). (Images courtesy of Dr J Vencovsky.)

Figure 2 Cutaneous changes—heliotrope rash, periorbital oedema. This is a fairly typical rash on the upper and lower eyelids, often found together with oedema of the soft tissue around the eyes. It usually responds quickly to treatment. Reproduced with the patient's or parent's consent. (Images courtesy of Dr J Vencovsky.)

Figure 3 Relapse of rash around eyes (periorbital heliotrope rash) and in the face after this patient herself discontinued glucocorticoid treatment prematurely. Reproduced with the patient's consent. (Image courtesy of Dr J Vencovsky.)

Figure 4 Classic distribution of the rash in dermatomyositis. This is called the shawl sign, because it copies its distribution. (Images courtesy of Dr J Vencovsky.)

Figure 5 Rash in dermatomyositis often involves the face and chest in the shape of V. Note depigmentation on the chest which frequently occurs after some time during the course of the illness. Reproduced with the patient's consent. (Image courtesy of Dr J Vencovsky.)

Figure 6 Typical rash on the lateral part of the thigh (holster sign). (Images courtesy of Dr J Vencovsky.)

Figure 7 Periungual capillary changes. There is a dilatation of the nailfold capillaries, which may be accompanied by vessel dropout (A, B). In some severe and active cases, vasculitis and necrosis can be seen in the acral parts of fingers (B). This is more common in children but may occasionally be seen in adults also, as is in this case. (Images courtesy of Dr J Vencovsky.)

Figure 8 Mechanic's hands are defined as hyperkeratosis and scaling with frequent fissuring and cracking along the lateral and palmar aspects of the fingers. Usually the first and second fingers are affected most. Occasionally, the fissuring is deep and very painful. Sometimes the skin is just hard and looks dirty. Note also the Gottron's signs over the metacarpophalangeal joints. (Images courtesy of Dr J Vencovsky.)

Figure 9 Rash may occasionally be extensive—erythroderma, involving sun-exposed and non-sun-exposed skin. (Image courtesy of Dr J Vencovsky.)

Figure 10 Ulcers on the skin can appear in different locations. They originate from vascular changes to the epidermis and dermis and can be sometimes very deep and difficult to heal. Ulcers in two patients with dermatomyositis are shown. Ulcer (A) under the breast; (B) in the armpit. (Images courtesy of Dr J Vencovsky.)

Figure 11 *Livedo reticularis in a patient with dermatomyositis. (Image courtesy of Dr J Vencovsky.)*

Figure 12 *Calcinosis. Subcutaneous calcifications (usually not intramuscular) are more common in juvenile dermatomyositis than in adults. However, they can infrequently also be seen in adult polymyositis/dermatomyositis. It is a difficult condition to treat. When drug treatment fails, it is possible to remove some calcifications surgically (A). In some cases calcinosis is diffuse and no surgical removal is possible. Extensive calcinosis located under the skin of the torso in an adult patient with dermatomyositis led to problems with movement and with breathing (B). (Images courtesy of Dr J Vencovsky.)*

5.1.3 Lung involvement

The prevalence of lung involvement in IIMs varies from 5% to 90% depending on diagnostic methods used and population assessed. Dyspnoea and cough are the main suspect symptoms for lung involvement. Even if the most common pulmonary complication is ILD, also respiratory muscle weakness may aggravate dyspnoea. ILD can be detected by sensitive techniques such as lung high-resolution computed tomography (HRCT) (figures 13 and 14) and pulmonary function tests (PFTs) plus carbon monoxide transfer factor (DLCO). Lung HRCT may identify the underlying type and extension of interstitial involvement, occurring mainly in the form of Non Specific Interstitial Pneumonia (NSIP) (Kiely PD et al, 2013) and complicating in particular the clinical course of ASSD patients (Cavagna L et al, 2015*). Other less commonly observed patterns of interstitial involvement are organizing pneumonia (OP), usual interstitial pneumonia (UIP) and diffuse alveolar damage (DAD). PFTs may show a restrictive pattern and the DLCO is generally reduced since the early phases of lung involvement. In PM/DM, ILD onset may precede, be concomitant or follow the onset of myositis, whereas in ASSD it may occur also without myositis, with or without concomitant joint involvement (see paragraph 5.1.8)

ILD presentation is heterogenous. In the acute/subacute forms, dyspnoea begins acutely and progresses rapidly; an acute life-threatening onset is also possible. In chronic onset, dyspnoea begins insidiously and progresses slowly. Furthermore, lung involvement can be an instrumental finding only, without clinical correlates (asymptomatic onset), although the meaning of this form is uncertain. Responsiveness to immunosuppressive therapy varies between patients and according to different histopathological patterns and autoantibody profile.

Aspiration pneumonia is another serious lung manifestation that is related to an underlying oesophageal and deglutitory muscles involvement (see paragraph 5.1.6) and that may be worsened by the concomitant occurrence of a bacterial infection.

In patients with IIM who develop ILD, progressive pulmonary scarring and intrapulmonary hypoxia may ensue and over time leads to progressive pulmonary hypertension and right-heart strain. Right-heart failure and death may result, thus optimal treatment of myositis-associated ILD should be early and appropriately aggressive to prevent such complications. Lastly, growing attention is focusing on pulmonary arterial hypertension (PAH) in IIMs (Sanges S et al, 2016), a form of pulmonary hypertension not related to the extension of ILD, but related to the occurrence of a primitive vascular inflammation, such as in idiopathic PAH. This rare manifestation may respond to a combination of immunosuppressants and PAH specific treatments. The concomitant occurrence of ILD and PAH is another possibility, particularly in ASSD. This association dramatically worsens patients' prognosis (Hervier B et al, 2013).

Figure 14 CT scan of severe diffuse alveolar disease in a patient with antisynthetase syndrome. (Source: CRI (Club Rhumatismes et Inflammation, <http://www.cri-net.com>; image courtesy of Dr J Vencovsky.)

5.1.4 Musculoskeletal findings

Arthralgias and arthritis are common in IIMs, particularly in patients with ASSD. In these patients, arthritis may be the first disease manifestation, often previously misdiagnosed as primary inflammatory arthritis (e.g. rheumatoid arthritis), at least until the subsequent occurrence of muscle or lung involvement becomes overt. In fact, when arthritis occurs in IIMs, it affects mainly small joints of the hands and feet, and in the subset of ASSD it may be very similar to rheumatoid arthritis (see In depth Discussion 3).

5.1.5 Heart manifestations

Although clinically significant heart involvement is rare, subclinical involvement in IIMs is common. Subclinical manifestations are dominated by conduction abnormalities, arrhythmias and heart rate variability detected by ECG, and by diastolic dysfunction detected by Doppler echocardiography. An inflammatory myocardial involvement is possible, since inflammation similar to that seen in the skeletal muscle can occur also in the myocardium. Furthermore, patients with PM/DM have an increased risk of developing atherosclerotic coronary artery disease (from twofold to fourfold), that, along with the increased prevalence of traditional cardiovascular risk factor, explains the prognostic impact of heart involvement in IIMs (Schwartz T et al, 2016).

5.1.6 Gastrointestinal involvement

Swallowing difficulties are often reported in PM/DM and, in particular, in IBM. In most severe cases, palatal and pharyngeal weakness may lead to aspiration pneumonia. The pathophysiology is related to weakness in the tongue, palate and pharyngeal muscles or sometimes also, in the lower oesophagus. Even if oesophageal dysfunction assessment techniques in IIMs are not standardized, electrodiagnostic tests, fibre-optic endoscopic evaluation of swallowing and oro-pharyngo- oesophageal scintigraphy could be considered useful tools. An underlying oesophageal dysfunction should be carefully considered in all IIMs patients. Gastro-oesophageal reflux is common and it may occur in 15–50% of patients. Constipation, diarrhoea and stomach pain are common symptoms and may result from disturbed motility of the gut or from gastrointestinal tract inflammation. Vasculitis in the blood vessels of the gastrointestinal tract is rare but it may be complicated by intestinal bleeding.

5.1.7 Malignancies

In comparison with the normal population, patients with IIMs have a higher risk of malignancy. This is mainly evident in DM (30% of cases), in particular if men, in old age (Zampieri et al, 2010*) and with dysphagia (Kang EH et al 2016). The risk of malignancy is particularly increased in the first years after disease diagnosis. The type of cancers associated with IIMs are lung, ovary, breast, colon and non-Hodgkin lymphoma (Kang EH et al, 2016). In some cases the association between DM and malignancies may be a paraneoplastic phenomenon, and thus, if the cancer is successfully treated, DM manifestations resolves. However, in other cases the development of

myositis is subsequent to malignancy or, despite treatment of the underlying cancer, the IIM does not improve. For PM and IBM the association with malignancy is less common.

Screening for cancer is recommended in patients with DM at diagnosis, possibly yearly thereafter, in case of relapse or of refractory disease (see in depth Discussion 2).

5.1.8 Antisynthetase syndrome

Antisynthetase syndrome (ASSD) is a clinically distinct IIM subset, affecting adults at any age, mainly females (F:M=3:1), positive for anti-aminoacyl-transfer RNA synthetase (ARS) antibodies and characterized by a highly variable clinical picture. The most frequent anti-ARS antibody is the anti Jo-1, directed against the histidyl-tRNA synthetase, whereas other specificities are less frequently identified (eg, anti-PL7, PL12, OJ, EJ, KS, Ha, Zo, see section 6.5.1). ILD, myositis and arthritis represent the classic clinical triad of the disease, with frequencies ranging from 60% to 95% of cases in different casuistries. Fever, Raynaud's phenomenon (RP) and mechanic's hands (MHs) are other important manifestations, even if less commonly observed (up to 50% of cases). It has been recently shown that in anti Jo-1 positive ASSD, the clinical triad of the disease is rarely observed at disease onset and frequently encountered at last follow-up, thus indicating that the ex-novo occurrence of triad findings lacking at disease onset is typical of this disease. This is particularly evident in patients presenting with an isolated triad finding (Cavagna L et al, 2015*), arthritis in particular (Cavagna L et al, 2016). The ex-novo occurrence of fever, MHs and RP during follow-up increases of four-fold the risk for the occurrence of triad findings lacking at disease onset (Bartoloni E et al, 2017). ILD is the main prognostic factor in ASSD. Similarly to PM/DM, NSIP is the most frequent ILD pattern. Joint involvement, that will be discussed in the in depth Discussion 3, ranges from simple polyarthralgias to a symmetrical, erosive, rheumatoid factor and anti-cyclic citrullinated peptide antibody positive polyarthritis. In ASSD muscle involvement is clinically similar to that previously described for PM/DM. Due to the lack of well-established classification criteria, several patients that are generally diagnosed with ASSD (eg an anti-Jo1 positive patient with ILD and with an oligoarthritis) could be classified as Interstitial Pneumonia with Autoimmune Features (IPAF) (Scire CA et al, 2017). Differences in clinical spectrum presentation and evolution between anti-Jo1 and non-anti-Jo1 positive ASSD should be assessed on large casuistries, even if an isolated ILD seems to be more common in non-anti-Jo1 positive patients. Non anti-Jo1 positivity impacts patients' survival (Hervier B, et al, 2012). It is important to remember that anti-Ro antibodies (mainly anti-Ro52 kDa) and anti-ARS antibodies co-occur in about 50% of cases (Cavagna L, et al 2015), and that a cytoplasmic positivity of ANA is commonly observed in ASSD (Aggarwal R et al, 2016).

6 Diagnosis

The diagnosis of IIMs is based on clinical, laboratory and histopathological findings. IIM should be suspected in adult patients with symmetrical, proximal skeletal muscle weakness or in cases of typical skin findings. Skin manifestations are easy to recognise by physical examination. Gottron's and heliotrope rashes are DM-specific

manifestations and usually do not require histological confirmation. When muscle involvement is suspected, muscle biopsy could be indicated. Biopsy is usually performed in an area with active muscle involvement in the proximal muscles of legs or arms.

A careful differential diagnosis in cases of myopathy or increase of serum creatine kinase levels should be performed (box-1).

Box-1 Conditions that might mimic inflammatory myopathies or induce Hyper-Creatine-Kinase-Emia and that should be considered in the differential diagnosis of IIMS

- A. Genetic muscle disorders
 - a. Muscle dystrophies: limb girdle, Becker's Emery–Dreifuss, facio-scapulo-humeral, dysferlinopathy, distal muscle dystrophy and ocular muscle dystrophy
 - b. Congenital myopathies: mitochondria myopathy, nemaline myopathy and central core myopathy
- B. Neuropathies
 - a. Denervation: spinal muscle atrophy, amyotrophic lateral sclerosis
 - b. Others: Eaton–Lambert syndrome, myasthenia gravis, Guillain–Barré, chronic demyelinating neuropathy
- C. Metabolic myopathies
 - a. Glycogen storage disease: McArdle, acid maltase deficiency
 - b. Lipid storage disease
- D. Endocrine disorders
 - a. Hyperthyroidism
 - b. Hypothyroidism
 - c. Acromegaly
 - d. Cushing syndrome
- E. Hydroelectrolytic disorders
 - a. Hyperpotassaemia
 - b. Hypomagnesemia
- F. Infections
 - a. Viral myopathy (parechovirus type 3, parvovirus B19, Coxsackievirus, human enterovirus, HIV, etc)
 - b. Trypanosoma cruzi
 - c. Bacteria (pyomyositis)
- G. Toxic agents and drugs
 - a. Alcohol
 - b. Cocaine
 - c. (Hydroxy)Chloroquine
 - d. Cimetidine
 - e. Colchicine
 - f. Statins
 - g. Amiodarone
 - h. Anaesthetics (used for general anaesthesia, such as the volatile aesthetic agents and succinylcholine, associated with malignant hyperthermia, life-threatening condition)
- H. Myosin-loss myopathy (in patients admitted to Intensive Care Units, deep impact on prognosis)
- I. Non disease related conditions
 - a. Injuries
 - b. Intense physical activity
 - c. Intramuscular injections
- J. Others: granulomatous diseases
 - a. Sarcoidosis

6.1 Classification Criteria

Up to now no validated classification criteria exists, but a shared ACR and EULAR initiative is currently working on the release of new validated classification criteria. The criteria proposed by Bohan and Peter (Bohan and Peter, 1975) are the most widely used ones, but they have several limitations: they do not clearly specify how to exclude other forms of myopathy, they may misclassify IBM as PM, and muscular dystrophies with inflammation as PM, and each included criterion is not defined explicitly, resulting in criteria with high sensitivity and low specificity. Other criteria have been suggested by Tanimoto (Tanimoto K et al, 1995), having high sensitivity and low specificity, by Dalakas and Hohlfeld (Dalakas and Hohlfeld, 2003), having low sensitivity and high specificity, and by Targoff (Targoff IN et al, 1997), having high sensitivity and specificity (Table 1). In 2005, a Canadian group proposed a classification based on overlap syndrome features and autoantibody profile (Trojanov et al, 2005*), thus opening the perspective in the definition of IIMs by including these new and clinically relevant aspects.

	Bohan and Peter ¹	Tanimoto ²	Targoff ³	Dalakas and Hohlfeld ⁴
Muscle findings	Symmetrical, usually progressive weakness	Pain on grasping or spontaneous	Symmetrical, usually progressive weakness	Weakness with subacute onset, rapid progression, prevalently proximal
Muscle biopsy	Necrosis of type I and type II muscle fibres, Phagocytosis, Degeneration and regeneration of myofibers with variation in myofiber size, Endomysial, perimysial, perivascular or interstitial mononuclear cells	Inflammatory infiltrate, degeneration or necrosis of muscle, active phagocytosis, central nuclei, active regeneration	Necrosis, phagocytosis, regeneration, mononuclear inflammatory infiltrate	Compatible findings for PM (DEFINITE: primary inflammation with the CD8/MHC-1 complex and no vacuoles; PROBABLE: ubiquitous MHC-1 expression) or DM (perifascicular, perimysial or perivascular infiltrates; perifascicular atrophy)
Serum muscle-associated enzymes	CK, aldolase, LDH, transaminases	CK, aldolase	CK, aldolase, LDH, transaminases	CK, aldolase, transaminases
Electromyography	Short, small, low amplitude,	Electromyographic triad of myopathy	Short, small, low amplitude,	Myopathic pattern

	polyphasic motor unit potentials or fibrillation potentials even at rest or bizarre high frequency repetitive discharges			polyphasic motor unit potentials or fibrillation potentials even at rest or bizarre high frequency repetitive discharges		
Cutaneous findings	Characteristics rashes of DM	Heliotrope rash, Gottron's linear extensor erythema		Heliotrope rash, Gottron's papules		Typical rash or calcinosis
Auto-antibodies	X	Anti Jo-1		Any proven IIM-associated antibody		X
Articular findings	X	Non-destructive arthritis or arthralgias		X		X
Systemic findings	X	Fever or elevated CRP or ESR		X		X

Table 1: mainly diagnostic and classification criteria available for idiopathic inflammatory myopathies (IIMs), eg polymyositis (PM) and dermatomyositis (DM).

1 Bohan and Peter: definite PM if 4 criteria (excluding skin findings); probable PM if 3 criteria (excluding skin findings); possible PM if 2 criteria (excluding skin findings). Definite DM if skin findings + 3 criteria; probable DM if skin findings + 2 criteria; possible DM if skin findings + 1 criteria.

2 Tanimoto: definite PM if 4 criteria (excluding skin findings). Definite DM if skin findings + 4 criteria.

3 Targoff: Definite IIM if 4 criteria; probable IIM if 3 criteria; possible IIM if 2 criteria; differentiation between PM and DM is made by presence or absence of skin findings.

4 Dalakas and Hohfeld (diagnostic criteria): definite IIM if 4 criteria. **FIRST EXCLUDE all other myopathies by state-of-the art methods (this will change over time)**

6.2 Laboratory abnormalities

Creatine-kinase (CK) is the most useful serum enzyme for diagnosis and assessment of IIMs, but an increased serum CK level is not specific for myositis, as it may be raised in several conditions (see Box-1). Furthermore, normal serum CK levels vary in healthy people; men have higher levels than women and African-Americans higher levels than Caucasian subjects. CK levels are not always increased in patients with myositis, and for instance, 10–20% have CK levels within normal range when first tested, particularly patients with DM and IBM.

A critical concern is the serum tests used to detect myocardial sufferance, as CK-MB can be released from damaged cardiomyocytes and also from regenerating skeletal muscle fibres. In patients with myositis, without cardiac involvement, the CK-MB/total CK ratio may be >3%, which is a threshold commonly used to determine myocardial damage. A more specific marker for myocardial damage in patients with myositis is increased serum levels of cardiac isoform troponin I (cTnI). Also high serum levels of cTnT (e.g., >100 ng/L) detected by high sensitivity assays may point towards myocardial involvement.

Myoglobin is a skeletal and cardiac muscle protein released after tissue injury. It is sensitive as CK in myositis and serum levels vary with disease activity, but it is usually less readily available than CK. Myoglobin is filtered through the kidneys, with an increased risk of renal failure in case of high levels of serum myoglobin. This condition requires a strong hydration in order to force the diuresis and reduce the risk of kidney damage.

Other circulating muscle enzymes are lactate dehydrogenase, aspartate aminotransferase and alanine aminotransferase. On this basis, it is important to remember that the increase of aminotransferase enzymes should not only be considered as a condition secondary to liver diseases. Although these other enzymes are not muscle specific, they often correlate with CK in patients with myositis. Isolated lactate dehydrogenase levels may be a sign of haemolysis or a malignancy. Aldolase is another enzyme that can be used to verify muscle injury, but it is less muscle-specific than CK.

6.3 Electromyography

Diagnostic electromyography (EMG) is an essential part of the investigation of patients with suspect IIMs. The myopathic changes include myopathic motor unit potentials with or without spontaneous discharges and fibrillations. A pathological electromyogram with changes compatible with myopathy supports a diagnosis of myositis, but changes are not completely specific. Conversely, a normal electromyogram pattern does not preclude myositis, as myositis, and consequently EMG changes, may be focal. An advantage of EMG, however, is that several muscles can be examined during the same test session. The sensitivity to changes of EMG is uncertain, thus EMG is not recommended as an outcome measure for monitoring treatment. Certain neurological conditions can cause weakness and CK elevations—for instance, some rare neuropathic conditions and anterior horn cell disease, and so might mimic PM. Thus, and as for muscle biopsy, EMG should also be considered as mandatory to preclude occasional myositis misdiagnoses.

6.4 Muscle imaging

Ultrasound (US) was the first imaging tool used for muscle evaluation. Affected muscles usually appear to be normal or have an increased size and have low echogenicity, and raised perfusion in cases of acute muscular involvement. Echogenicity is increased and muscle size and perfusion are reduced in the chronic stage (Weber et al, 2009). Even if potentially useful (Haber GE et al, 2015), ultrasonography is not routinely used in the daily assessment of IIMs.

Muscle magnetic resonance imaging (MRI) is considered the 'gold standard' for the study of muscles in patients with IIM, providing a detailed anatomical view of the extent of muscle involvement and of potential sites for muscle biopsy. Symmetrical muscular oedema, particularly in the musculature close to the limbs, which correlates well with disease activity, is clearly seen in T2-weighted images and short tau inversion recovery (STIR)

(figures 15 and 16) (Del Grande et al, 2011*). In T1-weighted images, fatty atrophy of the musculature reflects the chronic phase of the disease.

Figure 15 Examples of MR images. Thigh muscles from patients with idiopathic inflammatory myopathies. Inflammation causes oedema, which is seen on images that suppress the signal from fat (short tau inversion recovery or T2-weighted image with fat suppression) as white matter. (A) Symmetrical involvement of extensors; (B) fasciitis may occasionally be seen; (C) continuing active inflammation in the atrophic muscles during long-term disease; (D) limited symmetrical inflammation only in musculus quadriceps femoris. (Images courtesy of Dr J Vencovsky.)

Figure 16 MR image (T2-weighted with fat suppression) in a patient with polymyositis who responded well to glucocorticoid treatment. (Images courtesy of Dr J Vencovsky.)

6.5 Muscle biopsy

Muscle biopsy in IIMs is useful for several reasons: (1) to confirm histologic muscle alterations of PM/DM; (2) to distinguish PM from IBM; (3) to exclude other myopathies such as dystrophies and metabolic myopathies, etc. A positive muscle biopsy is required for a definitive diagnosis of PM. In patients with skin changes characteristic of DM, the role of muscle biopsy in the diagnosis is questionable. A negative muscle biopsy does not exclude myositis, as inflammatory changes may be focal, and thus easily missed owing to sampling error.

To obtain optimal information from muscle biopsies, it is important to define: (1) the correct muscle biopsy site; (2) proper histological sampling; (3) proper handling of the biopsy specimen and (4) evaluation of the biopsy, which should be performed in a specialised laboratory with neuromuscular expertise.

1. The muscle selected for biopsy should preferably be symptomatic and not atrophic, as in muscles with severe atrophy it is more common to obtain samples with fibrosis and adipose tissue substitution. Muscle biopsy should be guided by imaging. MRI and US (if MRI is not available) can be used to localise areas with oedema suggestive of inflammation.
2. Several biopsy-sampling techniques are effective. A semi-open biopsy technique with conchotome, needle biopsy or open biopsy all give sufficiently sized biopsy specimens, as long as the operator is familiar with the technique. The advantage of the conchotome and needle biopsy techniques is that the trauma is minor allowing for repeated biopsies, if required during follow-up. Furthermore, several samples can be taken at the same time to ensure that an adequate amount of tissue is obtained for investigations. A drawback of the needle biopsy technique is that the cross-sectional area is smaller than for the other two techniques, and focal changes are more easily missed.
3. Proper handling of the biopsy specimens is essential to obtain optimal diagnostic information and to avoid artefacts, such as those due to ice crystal formation. The specimens should be frozen and the procedure should be agreed with the specialist neuromuscular laboratory where the samples are to be investigated. This is important as ice crystal artefacts preclude assessment of the biopsy. Frozen sections of muscle biopsy specimens are required for routine evaluations, both to identify the rimmed vacuoles seen in IBM and to carry out biochemistry and immunohistochemistry stainings, which must be performed routinely for several molecules depending on the clinical features and suspected diagnosis. More recently, immunoblot analyses have been introduced as a routine investigation to identify aberrations in proteins, such as those due to mutations in genes. They are also used to identify various muscular dystrophies that may clinically resemble myositis, such as limb girdle dystrophy and dysferlinopathy, which can sometimes have considerable inflammatory cell infiltrations in muscle tissue.

4. In view of the specialised nature of the analytical techniques required to assess muscle biopsy specimens, these should ideally be sent to a laboratory with specific expertise in myopathology and immunohistochemistry to obtain optimal information. For a clinician looking after myopathic patients, communication with a specialist neuropathologist is valuable to ensure that adequate investigations are performed on the biopsies. More recently, immunohistochemical staining for MHC class I antigens has been shown to be useful, adding information to the diagnostic procedure as a sensitive, although not specific, marker for myositis. Electron microscopy investigations require special fixation and are performed by the neuropathologist when clinically indicated. This technique is often required for identification of the tubular filamentous inclusions seen in patients with IBM.

6.5.1 Histopathology

The inflammation in myositis affects striated muscle but not smooth muscle. Occasionally, heart muscle may be involved. The cellular infiltrates of skeletal muscle are characterised by mononuclear inflammatory cells, mainly T lymphocytes and macrophages, but DCs, B lymphocytes and plasma cells can also be found. Other typical changes are degenerating, necrotic fibres and regenerating muscle fibres (figure 17). These are non-specific histopathological findings and may also occur in other muscle disorders. Atrophy of muscle fibres is a common and non-specific pathological finding, but if seen in a perifascicular distribution, it may be more specific, as this is predominantly seen in biopsy specimens from patients with DM, usually in a later phase of disease (figure 18). In patients with DM, the inflammatory infiltrates mainly have a perivascular and perimysial location and are dominated by CD4 T-cells and macrophages. Occasionally, B-cells are found. In PM the inflammatory infiltrates are mainly located in the endomysium surrounding muscle fibres. In these infiltrates there is a high prevalence of CD8 T-cells, but also CD4 T-cells and macrophages. The different localisation of the inflammatory infiltrates, perimysial versus endomysial, as well as the different predominating inflammatory cell types CD4 T-cells and CD8 T-cells, suggest that different disease mechanisms may cause myositis. These histopathological features are often confined to restricted muscle areas and in some cases a muscle biopsy specimen can result normal despite clinically evident muscle weakness. Furthermore, the extent of histopathological features does not correlate with the degree of muscle weakness. This observation is clinically important as a 'normal' looking biopsy specimen does not exclude a diagnosis of myositis. In addition, this raises the question regarding the mechanisms that cause muscle weakness in PM and DM, and what findings in the muscle correlate with symptoms. This will be discussed further below.

The histopathology of IBM resembles that of PM, with endomysial infiltrates with a predominance of CD8 T-cells and macrophages (figure 19). In addition, characteristic findings are rimmed vacuoles and intracellular amyloid deposits or 15–18 nm tubofilamentous inclusions found on electron microscopy. Early in the course of IBM, only the inflammatory infiltrates may be evident and the initial histopathology may be indistinguishable from that of

PM. If a patient labelled as having PM responds poorly to immunosuppressive treatment it is wise to consider a diagnosis of IBM, and to repeat the muscle biopsy.

6.6 Autoantibodies

Autoantibodies are a fundamental diagnostic tool, especially to confirm the diagnosis of IIM while contributing to the definition of disease subsets. Autoantibodies in IIMs are directed towards ubiquitous intracellular autoantigens. Autoantibodies are detected in about 60% of patients with myositis and are subdivided into two groups, based on their diagnostic accuracy: MSAs and MAAs, the latter mostly occurring in patients with myositis-overlap syndromes but also in connective tissue diseases without evidence of myositis (Ghirardello et al, 2013*).

6.6.1 Myositis-specific autoantibodies

MSAs are highly selective and mutually exclusive antibodies directed against cytoplasmic or nuclear components involved in the regulation of key processes, such as protein synthesis and translocation, gene transcription and viral recognition. The three best characterized antibodies target cytoplasmic enzymes (anti-ARS antibodies), the nuclear helicase protein Mi-2 and the cytoplasmic complex signal recognition particle (SRP). Moreover, several new MSAs have been recently described.

Anti-ARS antibodies are the most prevalent MSAs, found in 25–35% of cases and anti-Jo1 is the most common one (20–30% of myositis patients). Other less common specificities are represented by anti-PL7, PL12, OJ, EJ, KS, Zo and Ha (5% or less). All these antibodies are associated with a disease-related ILD, frequently isolated in anti-PL7 and PL12 positive patients (Hervier B et al, 2012). Casuistries addressed to non-anti-Jo1 anti-ARS antibodies are however, too little to allow firm conclusions. Anti-ARS antibodies positivity is associated with a reduced risk of concurrent neoplasm. Serum levels of anti-Jo1 (and of anti-Ro antibodies), correlates with disease activity levels of IIMs (Stone KB et al, 2007; Aggarwal R et al, 2016 b; Bauhammer J et al, 2016).

Anti-Mi-2 antibody, directed against a nuclear antigen with nucleosome remodelling activities, is an established serological marker of IIM, strongly associated with DM, in which it can be found in 10–30% of patients. Patients with anti-Mi-2 positivity usually have typical DM skin rashes such as Gottron's papules or sign, periorbital heliotrope rash, involvement of the neck and upper back ('V' and 'shawl' rashes) and cuticular dystrophies. These patients are less likely to develop cancer, ILD and polyarthritis and respond well to steroid treatment (Ghirardello et al, 2005; Hengstman et al, 2006b).

Anti-SRP autoantibody is reported in 4–8% of patients with IIM. There is evidence that the anti-SRP antibody identifies the so-called 'anti-SRP syndrome', a form of severe necrotising myopathy, clinically similar to PM, with rapidly progressive symptoms and poor response to treatment. Characteristic histopathological features consist of predominant muscle fibre necrosis and/or regeneration associated with scarce inflammation (Hengstman et al, 2006a*).

Anti-transcription intermediary factor 1 gamma (TIF1- γ) autoantibody is present in about one-fifth of DM patients with severe cutaneous involvement, and in ~50% of patients with cancer associated DM. Thus, if this antibody is present in a patient >65-year-old diagnosed with DM more thorough cancer screening is recommended. Anti-TIF1- γ is also found in about one-fifth of patients with juvenile-DM, where it is associated with aggressive skin ulceration without increased cancer risk (Fiorentino DF, et al 2013).

Anti-MDA5 (also known as the anti-CADM-140) antibody has been firstly described in Asiatic patients. It is associated with DM, mainly amyopathic, with cutaneous ulcers and rapidly progressive ILD (Narang NS et al, 2015).

Anti-NXP2 antibody is found in 25% of juvenile or adult DM, rarely in PM, and is associated with subcutaneous calcinosis, severe disease and muscle contractures. Juvenile-DM, severe cutaneous lesions, including calcinosis, and muscle contractures are the prominent features. An association with cancer has been observed in adults, especially in males (Fiorentino DF, et al 2013).

Anti-SAE antibody is directed against small ubiquitin-like modifier 1 activating enzyme A and B subunits, and is found in 8% of adult patients with DM characterised by severe skin disease, dysphagia and systemic features (Tarricone et al, 2012).

Anti-HMGCR (also known as anti-200/100 kDa) antibody was firstly described in a case series of patients with necrotising features at muscle biopsy. This antibody can be associated with statin use, but can also be found in patients who are not treated with statins (Musset L, et al 2015). The clinical phenotype of these patients resembles that found in patients with other forms of IIMs: proximal muscle weakness, markedly raised CK, myopathic features on EMG and good response to immunosuppressive therapy.

MSAs have a high specificity for IIM, and might thus be helpful for confirming the diagnosis, but their sensitivity is low. Most MSAs can be detected only by immunoprecipitation, which is time consuming and costly and only available in a small number of research laboratories. The recent availability of new tools (ELISA and Immunoblot assay) able to identify a large number of MSAs (and of MAAs) (Muro Y et al, 2013; Bundel C et al, 2016; Cavazzana I et al, 2016;) allows the detection of a large number of patients positive for MSAs, with a relevant diagnostic impact. Anti-Jo1 antibodies are the only anti-ARS antibodies tested in the majority of routinely available ENA screening tests.

Details of the MSAs detectable by immunoprecipitation are summarised in table 2.

Although it is well established that anti-ARS antibodies are significantly associated with the HLA-class II DRB1*0301-DQA1*0501-DQB1*0201 haplotype, and anti-Mi-2 antibodies are significantly associated with the HLA-class II DRB1*0701-DQA1*0201-DQB1*0201 haplotype, it has not been established yet whether the rarer MSAs described are also associated with specific HLA-class II haplotypes.

Table 2 Currently detectable myositis-specific autoantibodies, their target autoantigens and clinical associations. (Adapted from Betteridge et al, Arthritis Res Ther 2011;13:209)

Autoantibody	Target autoantigen	Clinical associations	Frequency	
			Adults (%)	JDM (%)
Anti-ARS	Aminoacyl-tRNA synthetase	Antisynthetase syndrome:	Overall: 30–40	Overall:
- Jo-1	Histidyl -	Myositis	Jo-1: 15–20	1–3
- PL7	Threonyl -	ILD	PL7: 2–5	
- PL12	Alanyl -	Raynaud's phenomenon	PL12: 2–5	
- OJ	Isoleucyl -	Arthritis	OJ: <2	
- EJ	Glycyl -	Mechanic's hands	EJ: 2–5	
- KS	Asparaginy -	Fever	KS: <2	
- Ha	Tyrosyl -		Ha: <1	
- Zo	Phenylalanyl -		Zo: <1	
Anti-Mi-2	Nucleosome remodelling deacetylase complex	DM with hallmark skin changes	10–15	<1
Anti-TIF-1γ	Transcriptional intermediary factor 1 gamma	JDM: DM and skin ulceration Adults: DM and malignancy	13–21	23
Anti-MJ/NXP2	Nuclear matrix protein 2	JDM: DM and calcinosis Adults: DM and malignancy	<5	25
Anti-SAE	Small ubiquitin-like modifier activating enzyme (SAE)	DM	8	<1
Anti-MDA5	Melanoma Differentiation Associated gene5 (MDA5)	JDM: DM and ILD Adults: CADM and ILD	<5 (50–70 in CADM)	7–38
Anti-SRP	Signal recognition particle (SRP)	Necrotising myopathy	4–8	<1
Anti-HMGCR	3-Hydroxy-3-methylglutaryl-CoA reductase (HMGCR)	Statin-induced necrotising myopathy	<10 Necrotising myopathy	Unknown

CAADM, clinically amyopathic dermatomyositis; DM, dermatomyositis; ILD, interstitial lung disease; JDM, juvenile dermatomyositis.

6.6.2 Myositis-associated autoantibodies

MAAs are often found in patients with an overlap-myositis condition (eg, associated with other CTDs). The MAAs include anti-Ro52 kDa, anti-La (linked to anti-Ro), anti-PM-Scl (75 and 100 kDa), anti-RNP, and anti-Ku antibodies.

Anti-Ro52 kDa antibody is found in more than 30% of patients with myositis and, as previously stated, it is often associated with anti-ARS antibodies. This association suggests that (auto) antigenic Ro particles might participate in the priming/sustaining of muscle/lung tissue damage and, potentially, also of joint damage. Nevertheless, the clinical relevance of anti-Ro52 antibody in patients with myositis has not been fully elucidated, even if clinical presentation pattern and evolution, as well as survival were not influenced in a large casuistry of patients (*Cavagna L et al, 2015).

Anti-PM-Scl antibodies are frequently detected in adult patients whose myositis occurs in association with systemic sclerosis dermal and pulmonary features. In juvenile-DM, a proportion of cases will lose the characteristic DM rash found at disease onset, only to develop scleroderma features over time. These cases often prove positive for anti-PM-Scl antibodies, and the term, scleromyositis, has been invented for this differentiated phenotype. With respect to anti-PM/Scl-100 antibodies, the anti-PM/Scl-75 ones have been detected more frequently in younger and more active patients with joint contractures (Hanke K et al, 2011).

Patients with anti-RNP antibodies can have myositis as part of mixed connective tissue disease, while anti-Ku-positive patients can have myositis overlapping with systemic sclerosis or SLE.

7. Inclusion body myositis

IBM was identified as a subset of IIM in the 1960s based on specific histopathological findings, including sarcoplasmic and nuclear inclusions and rimmed vacuoles. Epidemiology has been reported in paragraph 2. The sporadic, non-familial, form of IBM is more common in men than in women and is mainly seen in people aged >50 years. Also hereditary forms of IBM have been detected, surely linked to a various and still to be established different genetic backgrounds (see paragraph 3.1). The characteristic clinical phenotype consists of muscle weakness with an insidious onset (over months to years) with an average diagnostic delay of 6 years. Weakness of knee extensors and of distal muscles, particularly of the forearms and of the hands, resulting in finger flexor weakness, are typical of IBM. The most common symptom is difficulty with walking, and the progressive weakness of knee extensors frequently causes falls during deambulation. IBM is not a painful disease. Creatine kinase levels can initially be elevated up to 10-fold, but they remain only slightly elevated as the disease progresses. The course of the disease is slowly progressive, leading to muscle atrophy that can be striking, particularly at the level of knee extensors and forearm muscles. Severe generalised weakness, including that of the swallowing muscles, may lead to premature death. Extra-muscular involvement is rare. Subsets of patients with IBM do not initially have the classic peripheral weakness of finger flexors and forearms and are often misdiagnosed as having PM. Initial biopsies in such cases often do not reveal the diagnostic inclusions; thus, multiple repeated biopsies over time are often required before these characteristic changes become apparent.

Autoantibodies are present in 30% of patients and in half of these, MSAs/MAAs can be detected. More recently, anti-NT5C1A antibodies, targeting the cytoplasmic 5' nucleotidase muscle specific protein, have been described at high levels in about 30-60% of patients with IBM. This antibody is rare in PM (5%), thus helping in the differential diagnosis. However, these antibodies can also be found in 14-20% of patients with DM, SLE or Sjögren's syndrome. Thus, the clinical relevance of this new antibody as a biomarker is still under investigation (Greenberg, 2013). IBM may be associated with inflammatory CTDs such as Sjögren's syndrome, SLE, systemic sclerosis or with interstitial pneumonitis.

IBM is generally refractory to immunosuppressants (see paragraph 9.5). Thus, a diagnosis of IBM should always be considered in treatment-resistant cases of PM. By considering this characteristic along with a common genetic background with some neurodegenerative disorders (see paragraph 3.1), it has been questioned whether IBM is an autoimmune disease or rather a degenerative muscle disease supported by abnormal accumulation of proteins, such as amyloid- β , in muscle fibres.

8 Clinometric measurements

A critical part of the clinical evaluation of IIMs patients is to distinguish the signs and symptoms due to disease activity or disease damage. Disease activity is reversible with treatment, whereas damage is often irreversible and cumulative.

Recently, two international collaborative groups, the International Myositis Assessment and Clinical Studies Group (IMACS) and the Paediatric Rheumatology International Trials Organisation (PRINTO) have defined a core set of measures to assess disease activity and disease damage in IIMs (box-3). Tools are posted in the free of charge IMACS website (<http://www.niehs.nih.gov/research/resources/imacs/diseaseactivity.cfm>) . Many of the core set measures are now used in randomised controlled trials and in clinical practice.

Box 3 Disease activity and damage: IMACS core set measurements

Disease activity

- Physician global activity – VAS/Likert
- Patient/parent global activity – VAS/Likert
- Muscle strength—manual muscle test (MMT)
- Physical function—[C] HAQ, CMAS
- Laboratory—muscle enzymes
- Extramuscular activity—MDAAT

Damage

- Myositis Damage Index (MDI)
- Physician global damage—VAS/Likert
- Physical function—[C] HAQ

[C], childhood; CMAS, Childhood Myositis Assessment Scale; HAQ, Health Assessment Questionnaire; IMACS, International Myositis Assessment and Clinical Studies Group; MDAAT, Myositis Disease Activity Assessment Tool; VAS, Visual Analogue Scale.

8.1 Disease activity assessment tools

8.1.1 Physician and patient/parent global activity

The physician and patient/parent global activity assessments are based on information available at clinical evaluation (subject's state, medical history, physical examination, laboratory testing and therapies). Adult patients or parents of children with myositis completing the patient/parent assessments are asked to take into account the active manifestations: muscles, skin, joints, heart, lungs or other parts of the body that can improve

with treatment. The score is recorded on a 10 cm Visual Analogue Scale (VAS) or a five-point Likert scale rating. For the VAS rating, a score of 0–10 (down to 1 decimal place) is used, and for the Likert scale, a grade of 0 (no disease activity), 1 (mild disease activity), 2 (moderate disease activity), 3 (severe disease activity) or 4 (extremely severe disease activity) is used. The 10 cm VAS may have higher sensitivity and specificity than the Likert scale. However, the two scales correlate highly. To reduce potential bias, this measure should be assessed by experienced clinicians.

8.1.2 Manual muscle testing

Manual muscle testing (MMT) considers and measures muscle strength as part of the physical examination. The MMT score has been reported as a sum of the scores for the total number of proximal, distal (tested bilaterally) and axial muscle groups. However, in IIMs the number of muscle groups tested has not been standardised. Recently, a subset of eight muscle groups, which includes a combination of proximal, distal and axial muscle groups, has been proposed and validated by the IMACS group: neck flexors, deltoids, biceps, wrist extensors, gluteus maximus and medius, quadriceps and ankle dorsiflexors are considered and separately scored. Both the modified Medical Research Council (MRC) Muscle Strength Scale and the Kendall Grading Scale are used. The Kendall grades are shown in table 3, and MMT execution is explained in figures 20–27. MMT is a valid measure of strength, that should be routinely performed in the evaluation of patients with myositis. However, it does not discriminate between activity and damage, resulting in less sensitivity and specificity for patients with accumulated damage and progressive muscle atrophy.

Table 3 Kendall's 10-point Strength Scale. (Modified from Kendall FP, McCreary EK, Provance PG. Muscle testing and function. 4th ed. Baltimore: Williams & Wilkins, 1993)

	Function of the muscle	Score
No movement	No contraction felt in the muscle	0
	Tendons becomes prominent or feeble contractions felt in the muscle, but not visible movement of the part	1
Movement in horizontal plane (gravity-eliminated position)	Moves through partial range of motion	1
	Moves through complete range of motion	2
Movement against gravity	Movement through partial range of motion	3
	Gradual release from test position	4
	Holds test position without added pressure	5
	Holds test position against slight pressure	6
	Holds test position against slight to moderate pressure	7
	Holds test position against moderate pressure	8
	Holds test position against strong to moderate pressure	9
	Holds test position against strong pressure	10

Figure 20 Manual muscle testing: evaluation of neck flexors. (A) Antigravity position. With the patient supine and their arms at their side, the head is supported on the table. The therapist stands next to the patient's head and the testing hand is placed on the patient's forehead. The patient lifts their head off the table by flexing the neck and tucking the chin. The tester applies resistance at the forehead in the direction of capital and cervical extension and may position a hand underneath the subject's head for protection, or offer additional stabilisation across the abdomen (if needed). **(B) Gravity-eliminated position.** With the patient lying on their side and their arms remaining at their side, the head is supported on the table. The tester will support the head to prevent cervical side bending, provide stabilisation at the anterior shoulder as needed. The patient flexes the head and neck; the therapist neither assists nor resists the patient's voluntary movement. Patient consent obtained.

Figure 21 Manual muscle testing: evaluation of deltoid. (A) Antigravity position. With the patient sitting, the elbow should be flexed to indicate the neutral position of rotation. The therapist should stand at the test side of the patient and place pressure against the dorsal surface of the distal end of the humerus. The patient has to maintain the arm in abduction against gravity and tester pressure. **(B) Gravity-eliminated position.** With the patient supine, the arm is abducted to 90° but is supported on the table with the elbow slightly flexed. The patient attempts to abduct the shoulder by sliding the arm on the table without rotation at the shoulder. The tester will support the arm to minimise the friction between the arm and the testing surface, and provide stabilisation at the upper trapezius, if needed, and instruct the patient to fully abduct the arm; the therapist neither assists nor resists the patient's voluntary movement. Patient consent obtained.

Figure 22 Manual muscle testing: evaluation of biceps. (A) Antigravity position. With the patient sitting the elbow is flexed at a right angle, with the forearm in supination. The therapist should stand in front of, and at the testing side of, the patient. The hand giving resistance is contoured over the flexor surface of the forearm just proximal to the wrist. The other hand is applied to the humerus to provide a counterforce. The patient flexes the elbow against the applied force. If the biceps/brachialis are weak the patient will pronate the forearm before flexing the elbow. **(B) Gravity-eliminated position.** With the patient sitting with 90° shoulder abduction or lying on the side, the elbow is fully extended. The therapist should stand at the test side of the patient and support the abducted arm under the elbow and wrist, if necessary. The patient attempts to bend the elbow with the hand supinated; the therapist neither assists nor resists the patient's voluntary movement. The side-lying position may be preferred for subjects with limited range of motion at the shoulder. Patient consent obtained.

Figure 23 Manual muscle testing: evaluation of wrist extensors. (A) Antigravity position. With the patient sitting with the elbow and forearm supported, the forearm is in full pronation with the fingers flexed. The therapist should stand or sit in front of the patient and support the patient's forearm under the wrist while the other hand used for resistance is placed over the dorsal surface of the metacarpals. Full extension of the fingers is not allowed. **(B) Gravity-eliminated position.** With the patient sitting, the elbow and forearm are supported and the forearm is in a neutral position. The therapist should stand or sit at the test side of the patient and support the patient's wrist. This raises the hand from the table and removes friction. The patient extends the wrist; the therapist neither assists nor resists the patient's voluntary movement.

Figure 24 Manual muscle testing: evaluation of quadriceps. (A) Antigravity position. With the patient sitting with the trunk approximately perpendicular to the floor, the leg is extended—but not locked in extension at the knee. Trunk extension is allowed only if significant hamstring tightness precludes assuming the recommended testing position. The therapist stands at the side of the limb to be tested and the testing hand is placed over the anterior surface of the distal leg just above the ankle. The other hand is placed under the distal thigh. The patient extends the knee through the available range of motion. **(B) Gravity-eliminated position.** Side lying with the test limb superior to the supporting limb. The lower limb can be flexed for stability. Hold the test limb in about 90° of knee flexion with the hip in full extension. The therapist stands at knee level. One arm cradles the test limb around the thigh with the hand supporting the underside of the knee. The other hand holds the leg above the ankle. The patient extends the knee through the range of motion and the therapist neither assists nor resists the patient's voluntary movement.

Figure 26 Manual muscle testing: evaluation of the gluteus medius. (A) Antigravity position. With the patient side lying, the test leg is superior to the supporting leg. The test limb is slightly extended beyond the midline and the pelvis is rotated slightly forward. The supporting leg is flexed for stability. The therapist stands behind the patient and the test hand is placed on the lateral surface of the knee (A1) or at the ankle (A2), and the other hand is just proximal to the greater trochanter of the femur. The patient abducts against the applied resistance without flexing or rotating the hip. Resistance by the examiner is straight and downward. (B) Gravity-eliminated position. With the patient supine the therapist stands on the side of the limb to be tested. One hand supports and lifts the limb by holding it under the ankle. The patient abducts the hip through the available range of motion; the therapist neither assists nor resists the patient's voluntary movement.

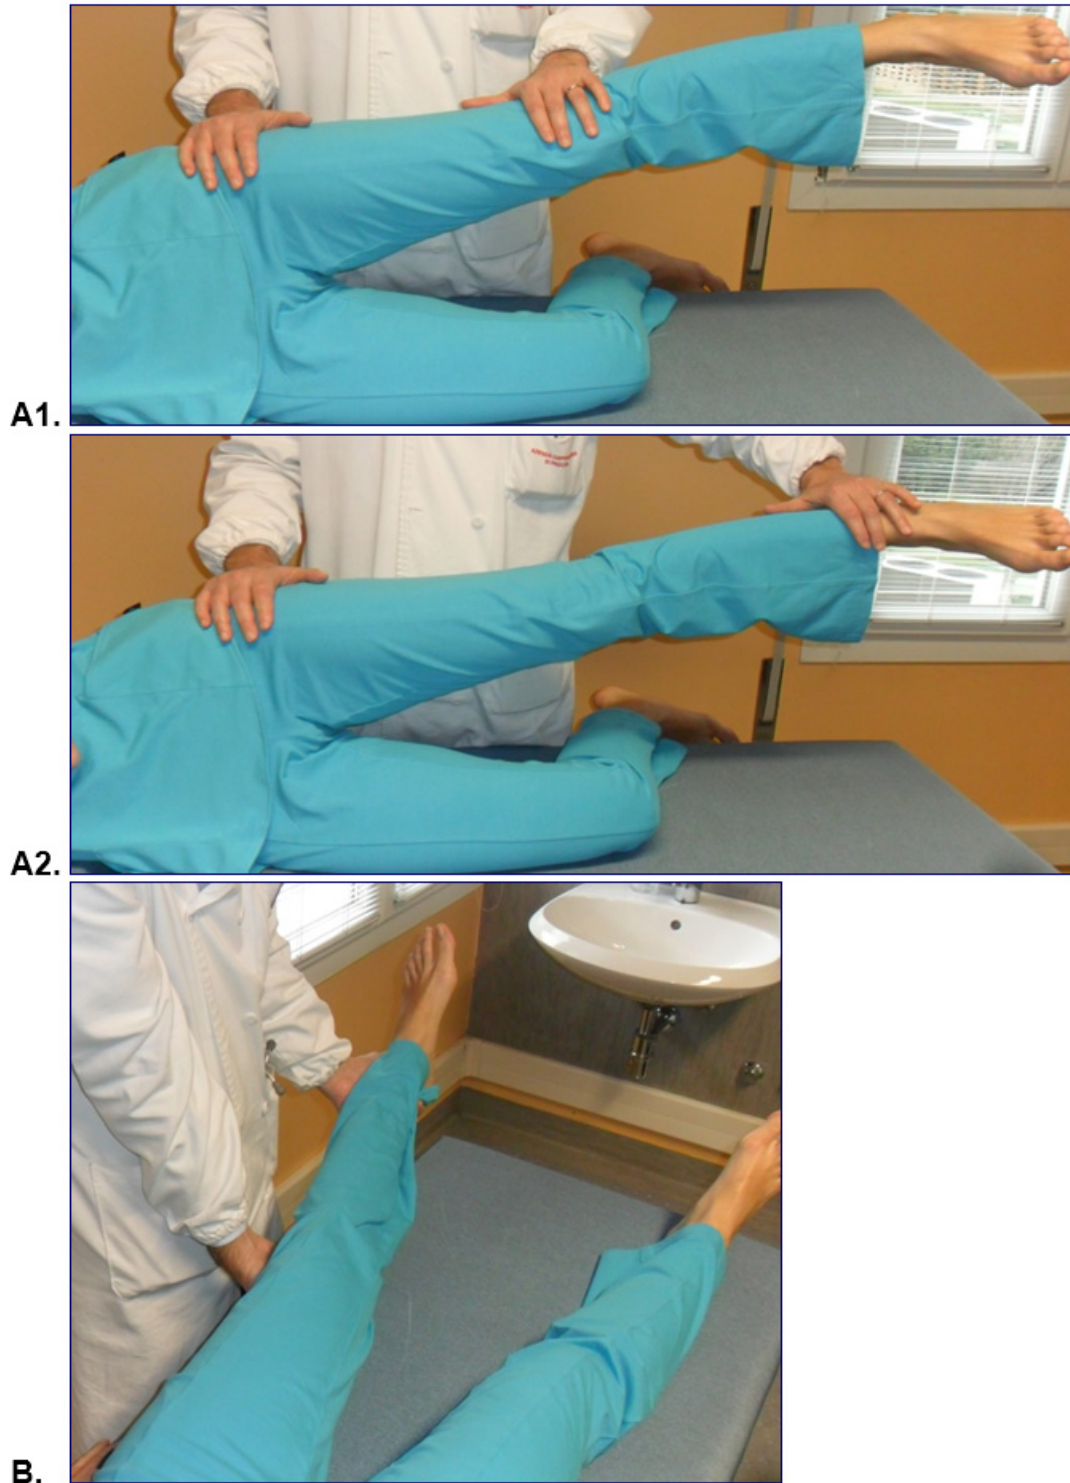

Figure 25 Manual muscle testing: evaluation of ankle dorsiflexors. (A) Antigravity position. With the patient sitting, the knee is flexed at 90°. The therapist sits at the side of the limb to be tested and supports the leg just above the ankle joint. The patient dorsiflexes the ankle joint foot without extending the great toe. Pressure is applied on the dorsum of the foot (in the direction of plantar flexion and eversion). (B) Gravity-eliminated position. Side lying with the test limb superior to the supporting limb. The lower limb can be flexed for stability. Hold the test limb in terminal knee extension with the hip in full extension. The therapist stands near the subject's feet and the supporting arm supports the test limb just proximal to the malleoli. The patient moves the foot from plantar flexion to dorsiflexion; the therapist neither assists nor resists the patient's voluntary movement.

Figure 27 Manual muscle testing: evaluation of gluteus maximus. (A) Antigravity position. With the patient prone and the knee flexed to 90° the therapist stands on the side to be tested and the testing hand is placed over the posterior thigh just above the knee. The other hand may stabilise the pelvis at the upper buttocks. The patient extends the hip through the available range of motion maintaining knee flexion at 90°. Resistance is applied directly downward toward the floor. (B) Gravity-eliminated position. With the patient side lying and the testing limb superior to the supporting limb, the knee is flexed and supported by the examiner. The supporting limb is flexed for stability. The therapist stands behind the patient and cradles the limb to be tested with forearm and hand under the flexed knee. The other hand is on the pelvis to maintain alignment. The patient extends the hip with the supported knee remaining flexed; the therapist neither assists nor resists the patient's voluntary movement.

8.1.3 Myositis disease activity assessment tool

The Myositis Disease Activity Assessment Tool (MDAAT) is a combined tool that assesses disease activity in muscular and extra muscular organ systems. It is based on an intention-to-treat approach modified from the British Isles Lupus Assessment Group (BILAG) used for patients with SLE. The MDAAT records symptoms and compares them with those seen in the previous month. It consists of two subscales: the Myositis Disease Activity Assessment VAS (MYOACT) and the Myositis Intention to Treat Activities Index (MITAX). The MYOACT scores seven organs/systems, including constitutional, cutaneous, skeletal, gastrointestinal, pulmonary, cardiac and muscle disease activity using a 0–10 VAS scale. The MITAX scores each clinical feature in every organ or system using a scale of 0–4, where 0 = not present, 1 = improving, 2 = the same, 3 = worsening and 4 = new. After conversion through a specific scoring schema, the final score ranges from A to E for each system (table 4). The MDAAT is a difficult score and clinicians need specific training before using it.

Table 4 Final Myositis Intention to Treat Activities Index score

Score	Description
A	Very active disease requiring treatment with high-dose daily glucocorticoids or significant immunosuppressive therapy
B	Need for modest doses of glucocorticoids and/or continuing immunosuppression
C	Need for low-dose glucocorticoids or symptomatic drugs only
D	The system is no longer active
E	The system has never been active

8.1.4 Treatment response criteria

ACR/EULAR criteria for minimal, moderate, and major clinical response in PM/DM have been recently published. Previously validated IMACS myositis core set measures have been included in the assessment (physician and patient global activity on a 10-cm visual analogue scale, muscle strength measured by MMT, physical function measured by the Health Assessment Questionnaire (HAQ), extramuscular global activity measured by the physician on a 10-cm VAS, and the most abnormal serum muscle enzyme). Final myositis response criteria for are reported in Table 5.

Table 5 Final ACR/EULAR myositis response criteria

Included core set measures	Score of improvement
degree of improvement according to absolute percent changes	
Physician global activity	
Worsening to 5% improvement	0
>5–15% improvement	7,5
>15–25% improvement	15
>25–40% improvement	17,5
>40% improvement	20
Patient global activity	
Worsening to 5% improvement	0
>5–15% improvement	2,5
>15–25% improvement	5
>25–40% improvement	7,5
>40% improvement	10
Manual muscle testing	
Worsening to 2% improvement	0
>2–10% improvement	10
>10–20% improvement	20
>20–30% improvement	27,5
>30% improvement	32,5
Health Assessment Questionnaire	
Worsening to 5% improvement	0
>5–15% improvement	5
>15–25% improvement	7,5
>25–40% improvement	7,5
>40% improvement	10
Enzyme (most abnormal)	
Worsening to 5% improvement	0
>5–15% improvement	2,5
>15–25% improvement	5
>25–40% improvement	7,5
>40% improvement	7,5
Extramuscular activity	
Worsening to 5% improvement	0
>5–15% improvement	7,5
>15–25% improvement	12,5
>25–40% improvement	15
>40% improvement	20

In order to calculate the total **improvement score** it is necessary to sum the 6 scores obtained in every item included. **Minimal improvement**: scores from 20 to 39, **moderate improvement**: scores from 40 to 59, **major improvement**: scores ≥ 60 . Adapted from Aggarwal R, et al. Ann Rheum Dis 2017;76:792-801.

8.2 Disease damage assessment tools

8.2.1 Myositis Damage Index

The Myositis Damage Index (MDI) measures damage in 11 organ systems. It includes 11 separate VAS 0–10 ratings that constitute the MDI severity of damage scale; the physician scores 0 when damage is absent and 10 in cases of extremely severe damage. Each system has also 3–6 items to be scored as absent or present (0 or 1, respectively). To receive a positive score, each item must be present for at least 6 months (or the pathology leading to feature must have been present for at least 6 months) despite prior therapies. The MDI measures the severity and the extent of damage both disease and comorbidities-related.

9 Prognosis and treatment

9.1 Prognosis

Before glucocorticoids use, patients with myositis had a high risk of developing deep muscle weakness, severe disability and premature death, mainly owing to pulmonary complications, such as aspiration pneumonia or ILD. Corticosteroids first, then immunosuppressants and biological drugs have substantially improved survival, quality of life and disability of IIMs patients. Mortality in patients with IMMIs still remains two- to threefold higher than general population; most common causes of death are cancer, lung and cardiac complications, and infections. With immunosuppressive treatment, about 75% of patients improve, but only 20–40% of treated patients can achieve disease remission and very few recover full normal muscle function, even in the absence of muscle inflammation. Moreover, 60–80% of treated patients have a polycyclic or chronic disease course. Poor prognostic factors in IIMs are older age, male gender, non-Caucasian ethnicity, longer symptoms duration, ILD, cardiac involvement, dysphagia, cancer and some specific serological patterns (anti-SRP, anti-155/140, anti-TIF1- γ , anti-NXP2, and anti-CADM-140 antibodies).

9.2 Pharmacological treatment

The low incidence and prevalence of IIMs and the lack of validated criteria for disease definition and assessment have severely hampered randomised controlled trials in these diseases. Thus, the effect of treatment in patients with IIM has been generally evaluated in open-label studies and case series. Recently, IMACS defined a consensus core set of measures to assess disease activity, disease damage and response to treatment, to be used in randomised controlled trials and in clinical practice (see paragraph 8.1.3 and 8.2)

9.2.1 Glucocorticoids

No placebo-controlled trials with glucocorticoids are available and the optimal dose and duration of treatment for patients with myositis are not standardised. High initial doses of glucocorticoids are recommended in PM/DM. IBM is usually non-responsive to steroids. Patients with PM/DM treated earlier generally have better

responses and outcomes. A high dose of prednisone or its equivalent (0.75–1 mg/kg/day) is recommended as starting dose, and should be maintained for 4–12 weeks. This recommendation is based on the observation of a maximal improvement of muscle function after an average of 12 weeks. Dose tapering usually begins after 1 month and is guided by improvements in muscle function and CK reduction. The recommended reduction is about 10–20% of the daily dose every month until the lowest effective dosage. Glucocorticoids should be used carefully, since steroid-induced side effects are major causes of disability in patients with PM/DM. Preliminary results showed the possible effectiveness and safety of low glucocorticoids doses (prednisone 0.5–0.75 mg/kg/day), but results need to be confirmed. Long-term treatment with glucocorticoids can also lead to steroid myopathy, which may occasionally be difficult to distinguish from active inflammatory disease. Box-4 shows some suggestions that may help in the decisions. Furthermore, glucocorticoids can lead to hypokalaemia, that may be associated with muscle weakness and thus interpreted as myositis disease activity. Topical glucocorticoids may be useful in controlling cutaneous manifestations

Box-4 Key characteristics of steroid myopathy

- Worsening of proximal muscle weakness—predominantly in the lower extremities
- Creatine kinase levels improved or normal
- Improvement with reduction of glucocorticoid dose
- No signs of active myositis on electromyography or MRI
- Selective atrophy of type II muscle fibres
- Increased urinary creatinine excretion
- Obvious extra muscular signs of glucocorticoid use: Cushing features
- Worsening of neck flexor weakness is an indicator of active myositis

9.2.2 Immunosuppressive drugs

The addition of immunosuppressant drugs to glucocorticoid regimens is indicated for most patients with PM/DM. Many experts recommend the introduction of immunosuppressive agents early in order to facilitate glucocorticoid dose tapering, especially in severe cases with poor prognosis. This might help to reduce long-term side effects, such as glucocorticoid myopathy, osteoporosis, cataracts, aseptic necrosis, etc. The prognosis is worse if treatment is delayed and therefore long-term and insufficiently suppressed disease activity should be avoided. Only a limited number of double-blind randomised controlled trials in small cohorts of patients with PM/DM have been performed.

Methotrexate is commonly used in PM/DM. Available data of effectiveness come from open trials, small cohorts and case report series. Methotrexate is used in dosages similar to those used in rheumatoid arthritis, up to 25 mg weekly, although the use of higher doses has also been reported. Mild pulmonary involvement due to myositis does not seem to be a contraindication for methotrexate. Even if data are lacking, Methotrexate is currently used also in case of joint involvement in IIMs. Anecdotal reports suggested their possible effectiveness on calcinosis, whereas no data are available for cutaneous involvement.

Azathioprine is commonly used in IIMs. Even if a 3-month, double-blind, prospective clinical study showed no differences between patients receiving glucocorticoids alone and glucocorticoids + azathioprine, the open-label extension of this study showed that patients in the combination group had better functional abilities and required less prednisone after 1 and 3 years. No data are available for azathioprine effectiveness in joint and cutaneous involvement, whereas some reports showed their effectiveness in ILD.

In myositis with ILD, several small case series suggest that **Cyclophosphamide** in *combination with glucocorticoids* has a good effect on pulmonary function, although randomised controlled trials have never been carried out. Recently, major clinical benefit without any evidence of serious toxicity was reported in severe and refractory juvenile-DM. Only few reports of cyclophosphamide effectiveness on cutaneous involvement are available. Data on joint involvement are completely lacking. Cyclophosphamide (1–2 mg/kg/day orally or better 0.75–1 g/m² IV per month for 5–6 months) is usually reserved for more severe cases, due to the high frequency of side effects.

Calcineurin-inhibitors (Cyclosporine, tacrolimus and pimecrolimus). Cyclosporine has been used in several open-label studies, with good results on ILD in different IIMs subsets. Cyclosporine has been effective on muscle involvement in an open, randomised, prospective study performed in juvenile-DM, even if with a slight trend in favour of methotrexate (the comparator) in some clinical and laboratory findings. Cyclosporine is currently used also in case of joint involvement despite the lack of current evidences. A recent systematic literature review evidenced the effectiveness of tacrolimus for both muscle and lung involvement in IIMs (Ge Y et al, 2015). No data are available for systemic cyclosporine and tacrolimus effectiveness on cutaneous involvement, but several reports on the effectiveness of topical formulations of tacrolimus (and pimecrolimus) are available.

The efficacy of **mycophenolate mofetil** has been recently suggested in patients with IIMs. Its use allowed reduction in glucocorticoid dose with a good safety profile. In small series and case reports, mycophenolate mofetil was used to treat PM/DM at a dose of up to 3 g a day, orally; an improvement of muscle strength was reported in up to 91.7% of cases. Some case series showed also the effectiveness of mycophenolate mofetil on ILD and cutaneous involvement in different subsets of IIMs.

Hydroxychloroquine has been recently suggested as a first line therapy for cutaneous involvement in juvenile dermatomyositis. Hydroxychloroquine is currently used also in case of joint involvement, but without supporting data.

The use of a combination of immunosuppressant agents has also been reported. One study compared the use of glucocorticoids alone or in combination with either methotrexate or cyclosporine, or all three agents together; the results suggested that the addition of both the immunosuppressive agents did not improve the outcome. A combination of methotrexate and azathioprine was studied in a prospective, randomised, open-label crossover study, which compared two aggressive approaches in patients with refractory IIM. Patients were

randomised to begin with either weekly oral methotrexate together with daily azathioprine or intravenous methotrexate with leucovorine rescue every 2 weeks for 6 months. Some patients from both groups improved with treatment and the analysis showed a trend in favour of those patients who first received oral combination treatment. A combination of oral cyclosporine A and intravenous cyclophosphamide has been used successfully in a limited number of patients with acute interstitial pneumonia.

Few cases reports of patients with PM and DM successfully treated with autologous stem cell transplantation have been reported. The results from the French multicentre phase I–II study included three patients with myositis; however, after 36 months no patient had responded, and two patients died. Interestingly, PM can occur in chronic graft-versus-host disease after allogeneic stem cell transplantation with higher incidence than expected by chance.

9.2.3 Intravenous immunoglobulins and apheresis

A double-blind, placebo-controlled, crossover trial in 15 patients with DM showed a significant improvement in muscle strength and neuromuscular symptoms at the end of the 3-month treatment phase in patients receiving intravenous immunoglobulin (IVIg) compared with those receiving placebo (Dalakas 1993). However, to maintain the clinical benefit patients required IVIg infusions every 4–8 weeks subsequently. A concomitant improvement of cutaneous rash has been also observed. Two other randomised, double-blind placebo-controlled trials were performed using IVIg in a few patients with PM/DM, showing conflicting results. Moreover, an open-label study of 35 patients with PM showed a disease improvement in >70% of cases, but seven of the 25 patients who responded well to IVIg treatment relapsed after an average time of 17.1 months (range 4–23 months) from the discontinuation of IVIg (Cherin P, 2002). IVIg treatment is well tolerated, since side effects are usually mild. In the placebo-controlled trial a second muscle biopsy carried out in patients with DM showed an increase in muscle fibre diameter, mean number of capillaries and downregulation of MHC I, intercellular adhesion molecule-1 and transforming growth factor β expression in the group treated with IVIg compared to those treated with placebo. By contrast, no difference in terms of CK decrease and MMT improvement between treatment arm and placebo was found in another placebo-controlled trial on 26 patients with PM (16) and DM (10) (Myasaka 2012). In some reports, IVIg has been reported as effective on ILD and on calcinosis complicating IIMs (Anh-Tu HS et al, 2017). Thus, the effects of high-dose IVIg in PM/DM remain unclear and their modes of action have not been fully clarified. Recently, subcutaneous administration has been proposed, showing good efficacy and safety. It could be an alternative of IVIg in patients with difficult venous access and in patients preferring home care setting (Cherin P et al, 2016) However, owing to the high costs and the uncertain effects, high-dose IVIg is rarely recommended.

Plasma exchange is used only in case of severe life-threatening manifestations and treatment-resistant cases.

9.2.4 Biological agents

Observations of immunological changes in the muscles of patients with PM/DM have stimulated interest in the biological treatment of these diseases. As expected, a number of immunologically relevant molecules have been identified in the inflamed muscles, such as TNF α , IL-1, adhesion molecules and many others, suggesting an active role of these molecules in the development of inflammation.

The expression of TNF α in PM/DM muscle tissue, increased TNF α serum levels and the known effects of TNF α on muscle metabolism, which include accelerated catabolism, contractile dysfunction and disruption of myogenesis, were the rationale for the treatment of patients with PM/DM with TNF inhibitors. However, TNF α exerts biphasic effects on skeletal muscle, promoting early myogenesis in undifferentiated myocytes and stimulating catabolism in more mature myotubes. On this basis the effectiveness of TNF inhibitors in IIMs could be questionable and the results available up to now seem to conform this hypothesis. In fact, even if some patients improved, in the majority of cases, treatment was not effective and disease relapsed or worsened. Furthermore, as previously stated (see paragraph 3.2.3), anti-TNF inhibitors were not able to avoid the subsequent occurrence of myositis in some ASSD patients presenting with an exclusive joint involvement at disease onset (Cavagna I et al, 2015)

Infliximab was effective in three patients with myositis (two PM, one DM), but not in one with DM who later developed non-Hodgkin's lymphoma. Dastmalchi et al (2008) reported a 14-week open-label study with infliximab in 13 patients with refractory disease (five PM, four DM, four sporadic IBM). The treatment was not beneficial and there was a high incidence of adverse events. Although three patients were defined as responders according to a composite disease activity score (IMACS), none had improved muscle strength according to the MMT. Two patients had increased disease activity and three had an increased signal in muscle MRI. Activation of the type I IFN system was recorded in several cases, suggesting a mechanism for the disease flares seen in some patients.

Efthimiou et al (2006) retrospectively described six patients with refractory PM/DM effectively treated with **etanercept** (response in five out of six). The response was mainly based on CK levels, but the method used to assess clinical improvement was not clearly reported. A recent study reported five patients with DM who all experienced an exacerbation of the disease during treatment with etanercept. A randomised, double-blind, placebo-controlled pilot trial evaluated the efficacy of etanercept (50 mg subcutaneously every week for 52 weeks) in 16 patients with DM. The authors found improvement of skin manifestations in 5/11 patients treated with etanercept and in 0/5 patients on placebo; however, skin manifestations worsened in five etanercept-treated and one placebo-treated subject. A recent pilot trial carried out with the use of etanercept in IBM did not show differences between patients treated with the biological drug and the control group. Moreover, a small

but statistically significant improvement in handgrip at 12 months was seen, which prompted the authors to suggest a large placebo-controlled trial of etanercept in IBM.

Altogether, these studies suggest that anti-TNF α blockade should not be recommended in IIMs.

IL-1 is largely expressed in the muscle tissue of patients with myositis and the IL-1 receptor antagonist (IL-1Ra), **anakinra**, has been suggested as a therapeutic option. However, few reports on the efficacy of this drug in the treatment of patients with IIM have been published. Anakinra was not effective in one patient with overlap between SLE and myositis, but it was effective in one anti-Jo1-positive ASSD with refractory polyarthritis and fever and in one patient with refractory anti-MDA5 clinically amyopathic dermatomyopathy. In an open-label study of 12 months performed on 15 patients with refractory IIMs (6 PM, 4 DM and 6 IBM) (Zong M et al, 2014), anakinra showed a favourable IMACS positive response in six patients with PM/DM and in one with IBM. Anakinra was not effective in a small pilot study performed on 5 patients with biopsy proven sporadic IBM (Kosmidis ML et al, 2013).

Two randomised pilot trials of interferon β -1a (IFN β -1a) have been performed in patients with IBM (Muscle study group 2001 and 2004). The treatment was well-tolerated, but no significant differences in muscle strength and muscle mass between placebo and IFN β -1a groups were seen at 6 months. IFN β -1a was effective in one patient with corticosteroid resistant PM (Dressel A and Beuche W, 2002). However, a case of severe dermatomyositis triggered by IFN β -1a therapy and associated with enhanced type I interferon signalling has been reported. The rationale for using IFN β -1a includes inhibition of T-cell proliferation, downregulation of T-cell activity, inhibition of IFN γ , IL-12, IL-1 and TNF α , reduction of antigen presentation in B-cells, inhibition of some adhesion molecules and chemokines. The potential concern in myositis might be the ability of IFN β to upregulate MHC I molecules or to rescue memory T-cells.

Depletion of B-cells has emerged as a new strategy in autoimmune diseases. Several case reports, case series and open-label studies showed the efficacy of **rituximab** (monoclonal antibody against CD20) in PM/DM. Oddis et al (2013) in a large multicentre randomised, double-blind trial treated 200 patients with refractory PM (76 patients), DM (76 patients) and juvenile-DM (48 patients) with early or late use of rituximab. The primary end point was the time to reach the IMACS 'definition of improvement', the secondary end point was the time to achieve >20% improvement in muscle strength. No differences were observed between treatment arms in the primary end-points, but the 83% of patients reached the definition of improvement and the components of the IMACS score improved throughout the 44 weeks of follow-up. A recent literature revision (Fasano F et al, 2017) including 48 studies and 458 patients showed that the rate of response to RTX was 78.3%, and the effectiveness was particularly evident in patient positive for MSA. Rituximab has been shown effective also in the treatment of ILD and of cutaneous involvement in different subsets of IIMs.

9.3 Non-pharmacological treatment

Combining exercise and immunosuppressive therapy is safe and has clear beneficial effects on muscle function (Alexanderson, 2009). The exercise should be tailored to the individual and supervised by a physical therapist to avoid overuse of muscles. In patients with IIMs, the combination of a 4-week standardized rehabilitation programme and a personalized, home-based, self-managed rehabilitation programme was well tolerated and had a positive medium-term functional effect. A multicentre, randomized controlled trial performed on 21 PM patients has been recently published (Tiffreau V 2017, et al). The intervention group participated in a 4-week standardized, hospital-based rehabilitation programme followed by a personalized, self-managed, home-based rehabilitation programme. The control group received physiotherapy on an outpatient basis. At 12 months, the intervention group had better scores than the control group for Health Assessment Questionnaire Disability Index, SF-36 (General Health and Role Physical items) and pain levels. Exercise combined with creatine supplement may have an advantage over exercise alone in improving muscle strength.

In case of cutaneous involvement the use of sunscreens is recommended, in order to reduce the risk of flares that may be induced by sunlight exposition.

9.4 Focus of IBM treatment

9.4.1 Pharmacological approach

IBM is usually regarded as non-responsive to glucocorticoids. There are occasional reported cases of 'stabilisation' for a period of months but this probably reflects the natural history of the disease. Prolonged administration of glucocorticoids in patients with IBM may lead to worsening of clinical aspects of the disease, despite improvement in CK levels and reduction of T-cell infiltrates on biopsy samples. Prednisone treatment increases the number of amyloid-containing fibres. Most experts support a brief use glucocorticoids in patients with inflammatory infiltrates at muscle biopsy, with an early association of more aggressive immunosuppressive treatments—for example, methotrexate or azathioprine, in patients with a coexisting connective tissue disease. Moreover, no change in muscle strength was found in patients treated with etanercept and infliximab. Data on anakinra and on IFN β -1a are limited but not satisfactory, whereas positive results have been obtained with alemtuzumab infusions. A trend towards improvement in dysphagia associated with IBM was reported in a small trial and case series on the use of IVIg, but the results have not been confirmed in long-term studies. Very promising results have been obtained with Follistatin Gene Therapy for mild to moderately affected, ambulatory sporadic IBM patients, with improvement of 6 minutes walking test in treated patients compared to a decline in untreated patients (Mendell JR et al, 2017). Two trials on stem cell transplantation (<https://clinicaltrials.gov/ct2/results?term=stem+cell+transplantation+inclusion+body+myositis&Search=Search> and <https://clinicaltrials.gov/ct2/results?term=stem+cell+transplantation+inclusion+body+myositis&Search=Search>) and arimoclomol (<https://clinicaltrials.gov/ct2/results?term=arimoclomol+inclusion+body+myositis&Search=Search>) have been

completed but results are not yet available. Bimagrumab inhibits activin type II receptors in the myostatin pathway and its use is supposed to increase muscle size in patients with IBM. Some trials on bimagrumab in IBM are currently ongoing (<https://clinicaltrials.gov/ct2/results?term=bimagrumab+inclusion+body+myositis&Search=Search>).

9.4.2 Non-pharmacological approach

No large randomized-controlled trials evaluating the effect of exercise in IBM are available to date, however, data from several small studies have been published and reported the safety of a low-to-moderate resistance programme. Although limited by small sample sizes and relatively short follow-up periods these studies also reported prevention of loss of muscle strength over time, improvements in strength, function, and aerobic capacity. Thus, a low-to-moderate exercise appears to be safe and may produce the benefit of mild increases or maintenance of strength and function. However, implementation of any exercise regimen should be supervised by a trained physical therapist.

Since falls frequently occur in patients with IBM due to knee collapse or tripping due to foot drop or uneven surfaces, the beneficial use of orthosis has been hypothesized. A specific stance control orthosis used in a small cohort of patients with IBM resulted in more stability and fewer falls. However, it caused a walking velocity and cadence slow down, which can limit its widespread use (reviewed by Alfano LN, 2015).

9.5 Summary of currently available treatment

Only a few controlled studies with small numbers of patients have been performed in IIMs. These trials, together with open studies and clinical experience guide treatment approaches. With the exception of IBM, glucocorticoids are the basis of treatment and methotrexate and azathioprine, also in combination, are up to now the best treatment options available for patients refractory to glucocorticoids. Other useful drugs are IVIg, calcineurin inhibitors, mycophenolate mofetil and hydroxychloroquine. Among biological agents, rituximab has been shown effective in PM/DM, in particular when MAS are positive. However, before planning PM/DM treatment, extra-muscular involvement should be carefully considered since this deeply influences the final decisions of clinicians. For this purpose, we reported the currently available treatment options and the correspondent areas of effectiveness in table 6. Further efforts should be performed in order to identify the optimal medical treatment of IBM.

Finally, there are accumulating data to support active exercise, in combination with pharmacological immunosuppressive treatment for improving outcome, both as performance in daily life and as muscle strength, compared with non-exercising patients. Exercise could be introduced early but should preferentially be individualised and designed by a physical therapist, and adjusted with improvements.

Table 6: list of drugs currently used in idiopathic inflammatory myositis ad relative areas of effectiveness.

SUMMARY POINTS

- Idiopathic inflammatory myopathies (IIMs) are rare autoimmune diseases caused by inflammation in striated muscles, leading to muscle weakness as the main symptom.
- Extra muscular involvement can often be seen, affecting mainly skin, lungs, joints, oesophagus and heart.
- Diagnosis of disease is based on clinical assessment, muscle imaging, muscle biopsy, electromyography, muscle enzymes increase and autoantibodies.
- About 10–15% of cases are associated with malignancy, more often in patients with dermatomyositis (DM).
- Serum autoantibodies can be found in about 60% of patients. These antibodies are often myositis specific and are associated with differential and distinctive clinical phenotype subsets within the growing IIM disease spectrum.
- Characteristic findings in the histopathology of polymyositis (PM), DM and inclusion body myositis (IBM) differ, probably reflecting variances in the pathogenesis of each disease.
- Core set measures for disease activity, damage and improvement are available.
- The mainstay of treatment is the use of glucocorticoids. These should be combined with other immunosuppressive drugs to reduce the side effects of high doses of glucocorticoids and to enhance the efficacy of immunosuppressive treatment, which often has to be maintained for prolonged periods.
- No definitive data on the efficacy of biological treatment are available. The use of rituximab is supported by several evidences
- Active physical exercise should be introduced early, and in combination with immunosuppressive treatment, and be guided by a physical therapist, based on individual ability.
- Prognosis is variable with some patients acquiring full strength, but with a majority of them having chronic disease with relapses and accumulating damage.

IN-DEPTH DISCUSSION I

**Interstitial lung disease and idiopathic inflammatory
myopathies**

Introduction

Interstitial lung disease (ILD) is the major contributor to morbidity and mortality in IIMs. It may occur both at disease onset (up to 65% of cases, Fathi M et al, 2004), and during the follow-up (Cavagna L et al, 2015), for a final prevalence of up to 85% of cases in some subsets. ILD-associated-IIMs may be related to various factors (infectious agents, drugs and chemicals), but in recent years evidence linked ILD to Myositis Specific Antibodies/Myositis Associated Antibodies (MSAs/MAAs). In fact, the positivity of some MSAs/MAAs is strictly associated with ILD occurrence (eg the antisynthetase antibodies) and relevant evidences suggested their pathogenetic role (Levine SM et al, 2007). Because of the lack of established classification criteria in some of the conditions belonging to Myositis Spectrum Diseases (ASSD for example), the majority of MSAs/MAAs have been enclosed in the recently published classification criteria for Interstitial Pneumonia with autoimmune features (IPAF) (eg, the antisynthetase antibodies, anti-PM-Scl, anti-Ro 52kDa, anti-RNP, anti-MDA5 antibodies). ILD presentation severity ranges from an acute onset, with the clinical picture of the respiratory distress syndrome, to an asymptomatic onset, in which lung involvement is only instrumental. It is important to remember that dyspnoea in IIMs may be related to several factors, reported in Table 1. We will focus only on ILD.

Diagnosis

Some examinations should be included in the routine assessment of IIMs, as for example pulmonary function tests (PFTs) + DLCO and lung high resolution computed tomography (HRCT). In case of ILD, PFTs + DLCO evidence a restrictive pattern ($FVC \leq 80\%$, $FEV1/FVC \geq 70\%$, decreased or normal FEV1 and/or $> 20\%$ reduction in DLCO) and these changes are useful for both diagnosis and monitoring of ILD. However, a restrictive pattern may be observed in patients with respiratory muscle involvement and DLCO reduction in patients with concomitant pulmonary hypertension. Even if chest radiograph remains in the routine assessment of IIMs, lung HRCT is the most sensitive technique for ILD detection in early stages and for the definition of the underlying type of ILD (Omote N et al, 2015). Fibre-optic bronchoscopy for bronchoalveolar lavage (BAL) may be useful in some cases, in particular when it is necessary to rule-out infections, such as pneumocystis, mycobacterium, aspergillosis and cytomegalovirus, drug-induced pneumonitis (eg, amiodarone, etc) and sarcoidosis. The use of surgical biopsy in IIM-ILD (CT-guided needle biopsy, or open lung biopsy, or video-assisted thoracoscopy) is generally limited to patients with concomitant lesions suspected for neoplasia. This is a possibility to keep in mind in patients with higher smoking pack-year number (**SHOOT INFORMATION:** Rheumatologists should become confident with this calculation: <http://www.smokingpackyears.com/>) and HRCT findings of emphysema (Enomoto Y et al, 2016). In all cases, please remember: 1) the potential morbidity associated with open lung surgical biopsy (Tazelaar HD et al, 1990). 2) the variation in histopathological interpretation of biopsies. 3) that histopathological findings may be non-specific and therefore non-diagnostic. 4) that HRCT findings can predict the histological appearance of ILD in open lung biopsy specimens (Fathi M et al, 2005). Even if a large number of serum biomarkers of ILD-IIMs

have been described (eg the mucin-like glycoprotein KL-6, serum B-cell activating factor, serum LIGHT Levels), they are mainly used in the research setting and not in the daily clinical activity. Lung echography is a new promising methodology not yet standardized that will become surely relevant in next years.

Computed tomography correlates of ILD in IIMs

Lung lesions are predominantly sub pleural, and in lower dorsal lobes, with involvement of one or two slices of secondary pulmonary lobules, with subsequent extension of lesions in case of disease progression (Franquet T et al, 2001). Even if, in previous years, some ILD extent scores have been proposed and used (eg the Kazerooni score), their role in the evaluation of disease evolution is actually questioned. The main histopathological forms of IIMs-ILD are non-specific interstitial pneumonia (NSIP) and usual interstitial pneumonia (UIP), with NSIP the most common type (Kiely PD et al, 2013). The main characteristics of **NSIP** is the temporal homogeneity of lesions, with prevalence of alveolitis (Ground-glass opacification aspect, GGO), homogeneous septal thickening and maintenance of the normal lobular architecture. The occurrence of GGO surrounded by bronchioloectasis has the meaning of micro reticular fibrosis (eg, fibrosis involving lobules). It is important to remember that also a fibrotic variant of NSIP exists (and it is extremely frequent), in which interstitial thickening is more due to uniform dense or loose fibrosis and mild chronic inflammation, and in which lung structures are still preserved. Occasionally, focal honeycomb fibrosis may be observed. On the contrary, the main characteristic of **UIP** is the temporal heterogeneity of lesions, with a patchy craniocaudal gradient of (irregular) peripheral septal thickening, bronchiectasis, ground glass opacities, and honeycombing. Lung architectural distortion, reflecting fibrotic changes, is another relevant characteristic of UIP. Organising pneumonia (OP, formerly bronchiolitis obliterans organising pneumonia) is another type of ILD observed in IIMs. It is characterized by patchy consolidation (from 2 centimetres to the entire lobe) with a predominantly sub pleural and/or peribronchial distribution, in which air bronchograms and bronchiectasis are common. These consolidations are frequently migrant even without treatment. **OP** may occur concomitantly to an underlying GGO, bronchial wall thickening, bronchial dilatation, mediastinal lymphadenopathy and pleural effusion. The HRCT pattern of Diffuse Alveolar Damage (**DAD**) is characterised by a diffuse Ground Glass aspect and it is typical of acute onset ILD. Some lung HRCT scans (NSIP, UIP and COP) are enclosed at the end of the chapter.

Autoantibodies and ILD in patients with IIM

Several MSAs and MAAs have been associated with ILD, as for example the antisynthetase antibodies, the anti-Ro 52 kDa, the anti-PM-Scl (75 and 100 kDa), the anti-Ku and, recently, the anti-MDA5 antibodies. We will focus on antisynthetase antibodies and on anti-MDA5 antibodies.

Anti-aminoacyl-tRNA synthetases

ILD is a common manifestation of patients positive for antisynthetase antibodies. Anti-histidyl tRNA synthetase (anti-Jo1) antibody is the most common anti-synthetase. Patients with anti-synthetase syndrome typically present with a combination of active myositis, ILD, fever, Raynaud's phenomenon and mechanics' hands. Patients with non-anti-Jo-1 anti-synthetase antibodies (PL-7, PL-12, EJ, OJ, KS, YRS, Zo) are keener to present with an isolated ILD, even if the trend for the ex-novo occurrence of other manifestations should be still assessed (more stable disease?). Surely, these patients have a worst prognosis with respect to anti-Jo1 positive patients (Hervier B, et al, 2012). The association with anti-Ro antibodies is common (50% of cases) in both anti-Jo1 and non-anti-Jo1 positive patients.

Anti-MDA5 antibody

Recently a novel MSA with a strong association to ILD has been identified: the anti-Melanoma Differentiation-Associated Gene 5 (anti-MDA5). This autoantibody has been reported in adult Japanese patients with a rapidly progressive lung disease, frequently without manifest muscle or other accompanying findings (Sato S et al, 2009). Lung involvement related to anti-MDA5 antibody has been associated with poor survival in US Patients with Amyopathic and Myopathic Dermatomyositis (Moghadam-Kia S et al, 2016).

Treatment

Established and evidence-based protocols for the treatment of IIM-ILD are not currently forthcoming and thus treatment is based on case series and case reports. Corticosteroids tend to be the first line of treatment as is the case in treating IIM in the absence of ILD. The typical initial dose is 0.75-1 mg/kg per day for 6-8 weeks and tapering once normalisation of CK and clinical parameters have improved.

As is the case with other more common autoimmune inflammatory rheumatic conditions, the current practice is to introduce steroid sparing agents to avoid the side effects associated with long term steroid use. The most frequently used include azathioprine, cyclophosphamide and cyclosporine. Methotrexate should be used in selected cases (eg, the occurrence of an articular involvement in IIMs), because associated to a potential lung toxicity. However, to have an ILD is not a complete contraindication to Methotrexate use (it is better to treat patients with stable and non-diffuse ILD). Depending on the extension of the ILD, an induction therapy with steroids or cyclophosphamide IV pulses can be performed, although there are no specific protocols for IIM, followed by a therapy with steroid or steroid-sparing drugs. Other newer agents that may potentially be of benefit include tacrolimus, mycophenolate mofetil and rituximab. Recently, some authors (Morisset J et al, 2016) proposed a treatment algorithm based on existing literature, that despite some limits should be considered a good starting point for further guidelines (see enclosed flow-chart).

Table 1. Spectrum of pulmonary involvement in IIM

Extrinsic lung disease	Intrinsic lung disease
Aspiration pneumonia	Interstitial lung disease
Infectious pneumonia	Non-specific interstitial pneumonia
Hypoventilation due to respiratory muscle weakness	Organising pneumonia
Congestive cardiac failure	Usual interstitial pneumonia
Pulmonary arterial hypertension	Diffuse alveolar damage
Pleuritis	Pulmonary capillaritis

Adapted from Schnabel A, et al. Curr Rheumatol Rep 2005;7:99-105.

Figure 1: note the homogeneous ground glass aspect identifiable in every scan (surrounded by yellow lines), without evidences of architectural distortions. This is typical for Non Specific Interstitial Pneumonia. Not all areas of involvement and normality have been surrounded by correspondent lines (courtesy of dr Lorenzo Cavagna).

Figure 2: note the heterogeneity of lesions, with concomitant ground glass areas (surrounded by light yellow lines), honey-combing (surrounded by red lines) and totally normal parenchyma (surrounded by blue lines) as typically observed in usual Interstitial Pneumonia. Not all areas of involvement and normality have been surrounded by correspondent lines (courtesy of dr Lorenzo Cavagna).

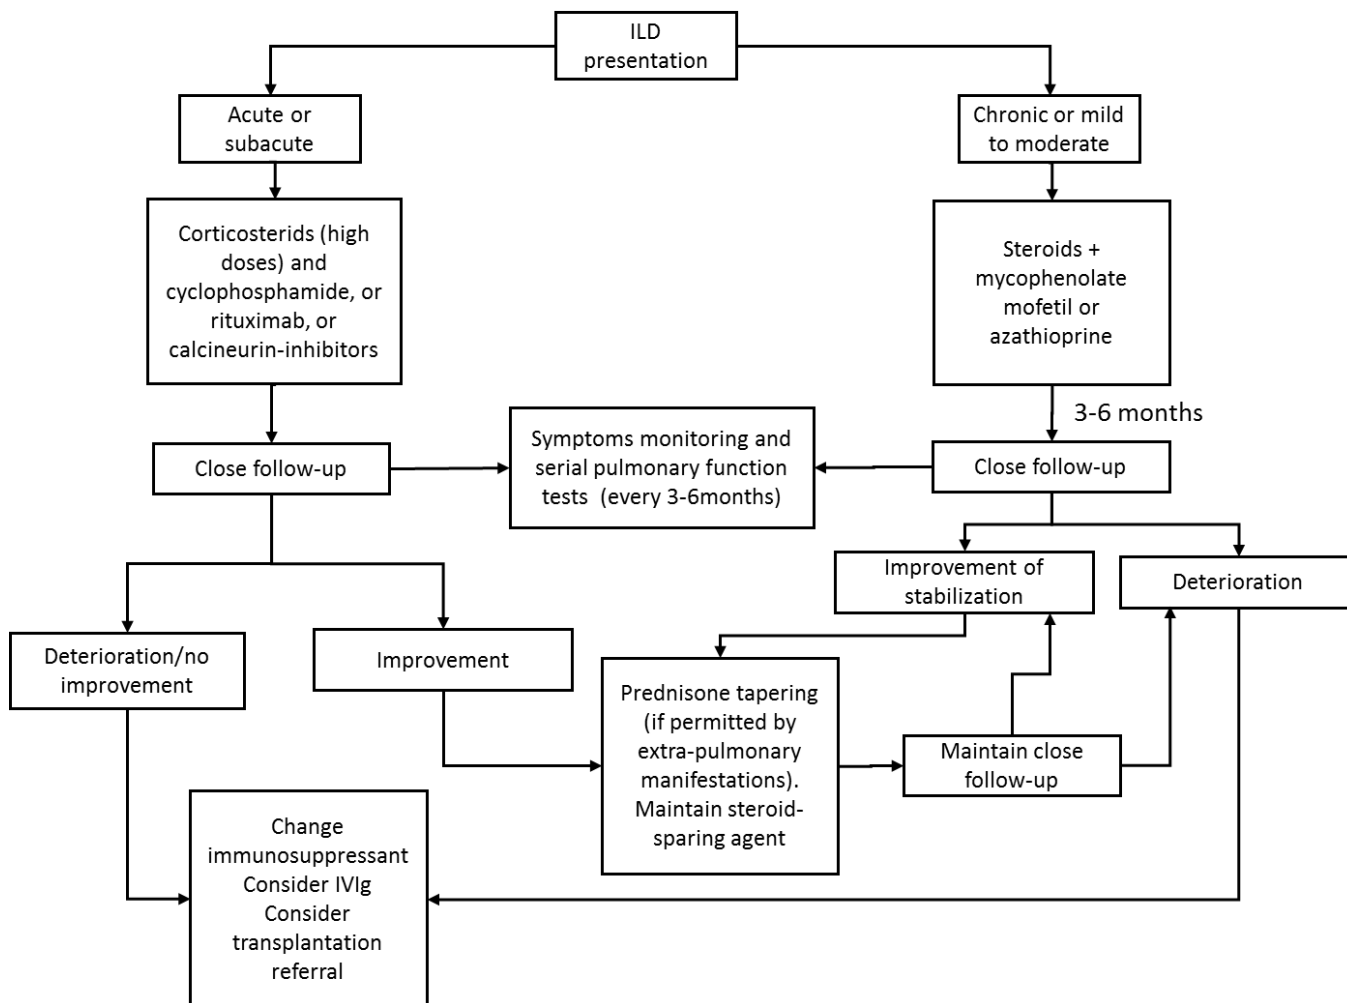

Figure 3: note the extended areas of consolidation in both lungs (courtesy of dr Lorenzo Cavagna)

Flow-Chart 1: proposed algorithm for ILD treatment in IIMs (Morisset J et al, 2016)

IN-DEPTH DISCUSSION II

Myositis and Cancer

Introduction

Cancer together with ILD is the major determinant of prognosis in IIMs. Surely, cancer deeply impacts the survival of affected patients and also their quality of life. The association between myositis and malignancy has been reported since 1916. Myositis can sometimes be a paraneoplastic syndrome due mostly to a solid tumour or complicate disease course. Old-males with DM, and concomitant dysphagias are at increased risk of cancer. In the subset of DM, an underlying neoplasm could be observed in up to 30% of cases. PM, ASSD and IBM seem to have a weaker association with cancer with respect to DM, but in comparison with the normal population, patients with IIM have a higher risk of malignancy.

Type of cancer associated with idiopathic inflammatory myositis

There is no specific cancer form associated with Idiopathic Inflammatory Myopathies (IIM). The most frequent association is with solid tumours, in particular lung, ovary, breast, and colon cancer. This study found an association also with non-Hodgkin lymphoma. However, a large amount of cancer types has been linked to IIMs in literature: oesophageal cancer, stomach cancer, pancreatic cancer, Hodgkin's disease, kidney cancer, and prostate cancer. In Asian populations, nasopharyngeal cancer was reported in patients with DM, but this is also a common form of cancer in the general population in Asia.

Clinical picture and autoantibodies

The clinical signs of paraneoplastic DM are quite similar to the classical one, although in patients with DM sometimes the skin rash can be very severe. Often, MSAs/MAAs are negative and CK is not elevated. Often it is not easy at DM diagnosis to differentiate paraneoplastic DM from a classical DM, based only on clinical or laboratory data. One way of determining that we are not seeing a typical DM is a poor response to treatment, even if aggressive. Thus, treatment resistance should raise awareness of a possible underlying malignancy. Recently, two novel autoantibodies, anti-TIF1- γ and anti-NXP-2, have been proven to be independently associated with cancer in IIMs. These antibodies occur in more than 50% of otherwise "antibody negative" patients. Testing for such antibodies should be recommended in the diagnostic work-up of cancer-associated DM; anti-TIF1- γ antibody is currently detectable by commercially available line blot assays. In general, in patients positive for anti-TIF1- γ , the diagnosis of cancer is generally performed within 1 year from myositis diagnosis. However, these antibodies are not specific for cancer associated DM, because they are also found in other DM cases, both in adults and children. Another factor of suspect for an underlying occult neoplasia is the occurrence of an autoimmune necrotizing myopathy: in particular, malignancies are more common in seronegative forms and in HMGCR-positive patients compared to anti-SRP positive patients. No specific type of cancer was predominant. The occurrence of anti-TIF1- γ and of autoimmune necrotizing myopathy is mutually exclusive. Even if other MSAs and MAAs, such as the antisynthetase antibodies, did not increase the risk of a concomitant

neoplasm, the screening for an occult neoplasia is indicated in all IIMs patients. Finally, we should remember a peculiar form of dermatomyositis, the so-called Wong's dermatomyositis, in which keratotic follicular papules, that may mimic pityriasis rubra pilaris, are associated with the typical muscle involvement of IIMs. This variant is frequently paraneoplastic.

Time of cancer appearance in patients with idiopathic inflammatory myositis

Myositis symptoms can precede or follow a cancer diagnosis, but most of them are diagnosed within one year of each other. A late onset of malignant disease could also be a late effect of the disease or its treatment.

When myositis symptoms appear before the cancer symptoms, there is the risk that they mask them and cause a delay in cancer diagnosis. It is also possible that aggressive treatment of myositis may worsen the outcome of the cancer. It is therefore easy to understand why cancer screening in all myositis patients, particularly in DM cases, is imperative. Furthermore, when myositis symptoms and signs follow a cancer diagnosis these should raise awareness of a possible underlying relapse of the cancer, even if the cancer was some years back and seemingly removed or cured. This is particularly evident in patients first presenting with a paraneoplastic myositis, in which the relapse of neoplasia is quite always associated with the relapse of myositis. On the contrary, if a cancer did not manifest concomitantly with a paraneoplastic myositis before, the risk of an ex-novo paraneoplastic syndrome in case of relapse is quite low. However, despite that, cancer screening in IIMS and in DM in particular is always mandatory.

How should we investigate patients with idiopathic inflammatory myopathies for an underlying malignancy?

Based on the known association between idiopathic inflammatory myopathies and malignancy, male patients with DM aged more than 50 years, are at higher risk for having an underlying cancer. Thus, these patients should be investigated with a carefully taken history and clinical exam, screening with usual blood and urine tests, chest x-ray, mammogram and gynaecology check-up (for females), prostate palpation, PSA, PSA-free (for males), stool examination, abdominal and pelvic scan. If any tests are aberrant they should be followed by more in depth examinations. Subsequent steps may involve CT scans (total body), total-body Positron Emission Tomography and other laboratory tests, according to the underlying suspect. In case of need, also invasive procedures should be considered, for instance anaemia should cause attention to a possible bleeding source in the gastro-intestinal tract due to cancer. It is important that neoplasm screening should be regularly performed not only at disease onset, but also during the follow-up, for at least 5-10 years, even if risk neoplasia is particularly increased in the first year after diagnosis.

Treatment of cancer associated idiopathic inflammatory myositis

If a solid tumour is diagnosed and it is possible to remove it by surgery, this could give a prompt resolution of DM symptoms without need of any further treatment. Unfortunately, not in all cases elimination of the cancer leads to remission of the myositis. In cases in which the complete elimination of cancer is not possible, treatment of the myositis should be done in collaboration with the oncologist to determine how aggressive myositis therapy should be. Active physical exercise should also be considered in combination with pharmacological therapy in these patients.

IN-DEPTH DISCUSSION III

Joint involvement in IIMs: available data

Even if joint involvement is a not rare finding in Idiopathic Inflammatory Myopathies (IIMs), no studies have been specifically aimed to arthritis pattern evaluation in these patients. Furthermore, joint involvement has been included exclusively in the Tanimoto Classification criteria for polymyositis/dermatomyositis (PM/DM), in term of non-destructive arthritis or arthralgias (see main document), but it is established that articular symptoms may range from simple arthralgias to destructive polyarthritis, also erosive, rheumatoid factor (RF) and anticyclic citrullinated peptide (ACPA) positive. In recent years, more attention has been put on joint involvement in antisynthetase syndrome (ASSD), in particular by the *French Club Rheumatisme et Inflammation* and by the *AENEAS collaborative group*. The results described by these two groups progressively changed the perspective of joint involvement in ASSD and suggested a more in depth analysis also in PM/DM, and in other Myositis specific antibodies (MSAs) and Myositis associated antibodies (MAAs) linked conditions (eg PM-Scl and scleromyositis). It is important now to focus on available data: in first reports on ASSD, joint involvement was considered mainly as a simple polyarthralgias, and joint erosions at plain X-rays were considered for long-time a rare finding. Only few reports suggested that RF test could had been occasionally positive in some ASSD patients, with subsequent troubles in the differential diagnosis with rheumatoid arthritis (RA). However, the first study specifically evaluating ACPA in ASSD patients and in IIMs in general, was published by Labrador-Horrillo et al in 2009. Even if positive test results were found in about 10% of patients, authors concluded that in the setting, ACPA may be considered as false-positive result and without clinical significance. However, in subsequent years, more reports described arthritis patients with RF and ACPA positive tests along with positive anti-synthetase antibodies (anti-ARS), with or without myositis or interstitial lung disease (ILD). In 2015, Lefèvre et al evidenced that ASSD may be revealed by a seronegative polyarthritis in 27% of cases. Of note, positive RF or ACPA, as well as the overlap with other connective tissue diseases was an exclusion criterion. Joint involvement pattern consisted mainly of a distal symmetrical polyarthralgia, with at least one joint with synovitis, or distal polyarthritis involving interphalangeal, metacarpophalangeal joints and wrists. Only 6% of patients had joint erosions at plain X-rays of hands and feet. Interestingly, Raynaud's phenomenon was observed in more than one third of patients and it was suggested as a red flag for the occurrence of ASSD in patients with seronegative and apparently isolated polyarthritis. Soon after this study, the same group evidenced that in ASSD, ACPA positive patients had a severe and erosive arthritis. The prevalence of ACPA in this study was 6% (17 out of 284 patients considered), but the occurrence of an isolated arthritis was one of the exclusion criteria identified by authors. All ACPA positive patients meet the 2010 ACR classification criteria for RA. In 2017, Cavagna L et al, described the characteristics of a large group of ASSD patients first presenting with an isolated arthritis. From the initial cohort of 243 anti-Jo1 positive ASSD, 58 (24%) were included in the study. Arthritis was mainly polyarticular (41 cases, 71%) and less frequently oligoarticular/asymmetrical (17, 29%). RF and ACPA were positive retrospectively in 39% and in 28% of evaluated patients, 35% had joint erosions at plain-X rays of hands and feet, and 47% showed the anti-Ro. Interestingly, the majority of patients (38, 65.5%) had arthritis as the only presenting clinical ASSD-related manifestation (no Raynaud's phenomenon, no fever, no mechanics hands)

and 22 (38%) were also anti-Ro negative. More than two third of patients satisfied the 1987 revised ACR classification criteria for RA, in particular all patients presenting with symmetrical polyarthritis. The first conclusion of the study was that the differential diagnosis between RA and ASSD is potentially troublesome because of several overlapping features, from the clinical, laboratory and radiographic point of view. But the most interesting finding observed was that quite all patients (with the exception of 5) developed myositis (65.5%) or Interstitial Lung Disease (ILD) (82%) or both (55%) during the follow-up, as confirmed in another subsequent study by Trallero-Araguas et al. These data showed the relevance of the early identification of antisynthetase antibodies and of ASSD in patients presenting with isolated arthritis, even when RA diagnosis is possible. Anti-Ro antibodies positivity (observed in 50% of ASSD patients), the cytoplasmic positivity of ANA test, and Raynaud's phenomenon occurrence, may be potential suspect findings for anti-ARS antibody positivity in patients with early arthritis. Furthermore, a multidisciplinary approach aimed at the early identification of muscle and lung involvement is mandatory in these patients. Based on this data, and as stated in the main text, it is possible that some cases of TNFi-induced anti Jo1 positive PM described in RA patients could be more related to the natural history of an ASSD rather than to TNF inhibitors (TNFi) therapy, as the anti-ARS positivity from arthritis onset suggest. In 2017, Gonzalez-Gay et al, evaluated if the timing of arthritis onset in ASSD (eg arthritis occurring at disease onset – Group 1, or developing during the follow-up- Group 2) could influence the presentation pattern of the manifestation. The study included 445 ASSD, mainly anti-Jo1 positive (366, 82%) but also non anti-Jo1 positive (79, 18%). The majority of these patients had arthritis from disease onset (367, 83%), whereas an ex-novo arthritis was less commonly observed (78, 17%). The data showed that arthritis characteristics are heterogeneous within the syndrome and influenced by the timing of onset. In particular, RA-like clinical, laboratory and radiologic features were more likely observed in patients presenting arthritis from disease onset and to a lesser extent in those presenting with an ex-novo arthritis during the follow-up. Conversely, fever, Raynaud's phenomenon and mechanic's hands were less common in patients with arthritis from disease onset when compared to patients with arthritis occurring after disease onset. On the other hand, the 1987 ACR revised classification criteria for RA were more commonly satisfied in Group 1 with respect to Group 2. From the serological point of view, anti-Ro antibodies were equally distributed among groups. According to these results and as recently suggested by the members of the French "Club Rheumatism and inflammation", it is possible to suggest that an overlap between RA and ASSD may occur in the first phases of the disease, whilst a "true" ASSD related arthritis manifests itself as a clinical feature during the follow-up. On this basis, it is evident that heterogeneity is the typical hallmark of arthritis in ASSD, that this heterogeneity may indicate different phenotypes of the disease with potentially different pathogenic mechanisms in various disease's phases. Of note, the final prevalence of arthritis in ASSD is about 70%. These results clearly showed how articular involvement in IIMs has been underrecognized and under evaluated for several years, even if potentially crucial in the assessment of these patients. More attention on articular involvement should be paid from now not only in ASSD, but also in IIMs in general.

Sjögren's syndrome and lymphoproliferations in autoimmune diseases

Cristina Vollenweider, Margarita Landi and Manuel Ramos-Casals

A previous version was coauthored by Pilar Brito-Zerón, Manuel Ramos-Casals and Athanasios G Tzioufas

LEARNING OBJECTIVES

- ➔ Outline the diagnostic process and current classification criteria used to define primary Sjögren's syndrome (pSS)
- ➔ List and describe the clinical features and laboratory findings in pSS
- ➔ Describe and evaluate the diagnostic methods used in pSS
- ➔ Explain and evaluate the various pathophysiological causes that have been suggested for pSS
- ➔ Explain the relationship between pSS and other autoimmune diseases and the risk of lymphoma
- ➔ List, outline and evaluate the variety of treatments available for the treatment of pSS

1 Introduction and classification

Sjögren syndrome (SS) is a systemic autoimmune disease that mainly affects the exocrine glands. This leads to dryness of the main mucosal surfaces, such as the mouth, eyes, skin, nose, pharynx, larynx and vagina (Ramos-Casals et al, 2012a). The disease overwhelmingly affects middle-aged women, but it may also affect children, men and the elderly. The clinical spectrum of SS extends from dryness of the main mucosal surfaces to systemic involvement (extra glandular manifestations) and includes a large number of manifestations. The variability in the presentation of SS may partially explain delays in diagnosis of up to 10 years from the onset of symptoms. It is a disease that can appear in many guises depending on the specific epidemiological, clinical or immunological features. It may be a serious disease with excess mortality, mainly related to extra glandular (systemic) involvement and haematological cancer. The main characteristics of the disease are summarised in box 1.

Box 1 Main characteristics of Sjögren's syndrome

- Sjögren syndrome (SS) is a systemic autoimmune disease that presents with sicca symptomatology of mucosal surfaces.
- The main sicca features (xerophthalmia and xerostomia) are determined by specific ocular (Lissamine green fluorescein or Rose Bengal staining and Schirmer test) and oral (salivary flow measurement) tests.
- The histological hallmark is a focal lymphocytic infiltration of the exocrine glands, determined by a biopsy of the minor labial salivary glands.
- The spectrum of the disease includes systemic features (extra glandular manifestations) in some patients, and may be complicated by the development of lymphoma.
- Patients with SS present a broad spectrum of analytical features (cytopenias, hypergammaglobulinaemia and high erythrocyte sedimentation rate) and autoantibodies, of which antinuclear antibodies are the most frequently detected, anti-Ro/SSA the most specific, and cryoglobulins and hypocomplementaemia the main prognostic markers.

When symptoms appear in a previously healthy person, the disease is classified as primary SS. When sicca features are found in association with another systemic autoimmune disease, most commonly rheumatoid arthritis (RA), systemic sclerosis (SSc) or systemic lupus erythematosus (SLE), it is classified as secondary SS; primary SS may also be associated with various organ-specific autoimmune diseases (box 2).

Box 2 Classification of Sjögren's syndrome (SS): primary and secondary SS**1. Primary SS****2. Secondary SS****2.1. Systemic autoimmune diseases**

Systemic lupus erythematosus
 Systemic sclerosis
 Rheumatoid arthritis
 Still's disease
 Sarcoidosis
 Inflammatory myopathies

2.2. Organ-specific autoimmune diseases/infections

Primary biliary cirrhosis
 Autoimmune Hepatitis
 Autoimmune thyroiditis
 Celiac disease
 Multiple sclerosis
 Diabetes mellitus
 Chronic viral infections
 Chronic HCV infection

 HTLV-I infection (Asian countries)
 HIV infection

2 Epidemiology

SS primarily affects white perimenopausal women, with a female:male ratio of at least 9:1. The disease may occur at all ages but typically has its onset in the fourth to sixth decades of life. An estimated 2–4 million people in the USA have SS, of whom about 1 million have established diagnoses (Helmick et al, 2008). Recent studies using the 2002 American–European Consensus Group (AECG) criteria have estimated a prevalence of 1–9 cases per 10 000 people in the general population of the greater Paris area (0.01–0.09%) (Maldini et al, 2014) and an annual incidence of 4.2 cases/100 000 people in the USA (Nannini et al, 2013).

A differentiated clinical and immunological expression has been reported for specific epidemiological subsets:

- Paediatric SS. SS might be diagnosed in children (Lieberman, 2013). More than 100 observations have been published, half of them concerning primary SS. In adults with primary SS, 5.5% of the patients reported

an onset of symptoms before the age of 16 years. In children, the average age of onset is 11 years. The female predominance is weaker than in adults, being between 73.5% and 80% (Cimaz et al, 2003). Parotid gland enlargement and recurrent parotiditis are the most common clinical features, whereas mouth and ocular dryness may appear later (Singer et al, 2008). The immunological pattern is identical to that of adults: antinuclear antibodies (ANAs) are detected in most cases and likewise anti-SSA antibodies are detected in 68–100% of children (Singer et al, 2008). Focal lymphocytic sialadenitis is not always present (Houghton et al, 2005). Thus these children will not always formally fulfil the AECG criteria developed for use in adult SS (Houghton et al, 2005; Singer et al, 2008). Lymphocytic infiltration of labial salivary glands and sialectasis are a consistent finding in all biopsies tested (Saad Magalhães et al, 2011).

- **Male patients.** Various studies have described a less pronounced clinical phenotype among male patients with SS than among female patients, including a lower frequency of abnormal ocular tests and a lower prevalence of positive ANAs, Raynaud's phenomenon and thyroiditis (Ramos-Casals et al, 2008). These findings are consistent with a generally accepted precept in autoimmunity—namely, that autoimmune diseases are more common in women, making diagnosis more difficult owing to this relatively muted presentation in men. IgG4-related disease (IgG4-RD) should always be considered in the differential diagnosis of male patients with sicca symptoms and salivary gland enlargement (Nocturne et al, 2011).
- **Elderly patients.** The prevalence of xerostomia increases with age and affects 30% of the population over 65 years of age. The presence of sicca syndrome is not necessarily associated with an autoimmune process and before performing other invasive or immunological tests, the first step is to discard the use of certain xerogenic drugs as the cause. Compared to younger patients, older patients have a lower frequency of serologic markers (anti-SSA, anti-SSB, Rheumatoid factor, hyperglobulinemia). Moreover, lung involvement and anaemia is more prevalent, whereas parotid enlargement, arthralgia and Raynaud phenomenon is less common (Baer et al. 2017)*.

3 Pathogenesis

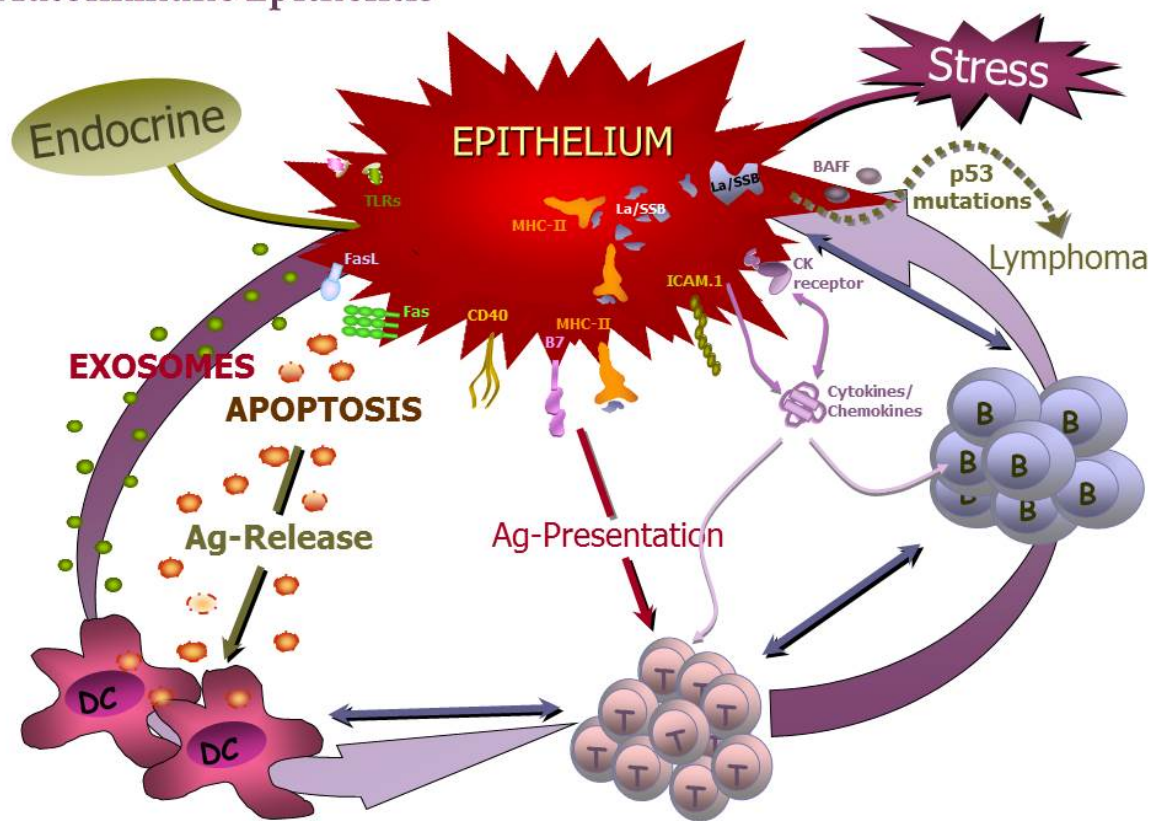

Primary SS is an excellent model for the study of autoimmune diseases since the targeted organs and cells (salivary gland epithelial cells and conjunctival epithelial cells) can be easily accessed and analysed (Voulgarelis and Tzioufas, 2010). Like all other autoimmune diseases, the origin of SS is unknown. Although, the interaction of genetic and environmental factors is being progressively unravelled (Fox, 2005) (figure 1).

Familial cases of primary SS are uncommon, but an aggregation of other autoimmune diseases is often seen. Polymorphisms of the early B cell factor 1, B cell lymphocyte kinase and tumour necrosis factor superfamily member 4 (TNFSF4) genes, all implicated in B cell differentiation and activation, have been recently associated with disease susceptibility (Nordmark et al, 2011; Ice et al, 2012). Interestingly, a gene polymorphism of interferon (IFN) regulatory factor-5, a transcription factor involved in IFN signalling pathway, is associated with

primary SS (Miceli-Richard et al, 2007) and additive effects of the major risk alleles of IFN regulatory factor-5 and STAT-4, both important mediators of type I IFN action, have been documented (Nordmark et al, 2009). Demonstration of the activation of the pathways of IFNs, potent antiviral proteins, sheds new light on the viral hypothesis; previous studies focused on the role of Epstein–Barr virus (EBV), herpesviruses, Cocksackie virus, retroviruses and hepatitis C virus (HCV). In addition, the epidemiological pattern of primary SS, overwhelmingly affecting women between the fourth and the sixth decade, strongly suggests the contributory role of hormonal factors.

Figure 1 Autoimmune epithelitis: pathogenesis of primary Sjögren's syndrome. (The figure is provided by Professor H M Moutsopoulos.)

Autoimmune Epithelitis

The epithelial cells play a central role in the pathogenesis of the immunopathological lesions. It appears that these cells are activated, producing a variety of cytokines and chemokines, as well as molecules able to prime local immune responses (HLA class II, costimulatory molecules and altered cellular distribution of autoantigen) (Tzioufas et al, 2012). Based on these observations, the term autoimmune epithelitis has been proposed (Moutsopoulos, 1994; Moutsopoulos, 2007).

Lymphocytes play a key role in the pathogenesis of SS. In mild lesions CD4+ T lymphocytes constitute the major cell population of invading cells (70–80%); whereas in more advanced lesions B cells predominate (Christodoulou et al, 2010). B cells in the lesions contain intracytoplasmic immunoglobulins with anti-Ro (SSA)

and/or anti-La (SSB) reactivity (Youinou et al, 2010). Oligoclonal B lymphocytes and germinal centre formation in salivary infiltrates (Theander et al, 2011; Risselada et al, 2013a) may represent a predisposing factor for lymphoma.

Macrophages and plasmacytoid dendritic cells, the professional type I IFN producers, have also been detected in minor salivary gland biopsy specimens from patients with SS. They are characterised by the presence of Toll-like receptors 7 and 9 (sensed by exogenous or endogenous nucleic acids), implying the presence of a viral or viral-like trigger at the level of salivary gland tissue. IFNs induce the expression of BAFF (B cell activating factor of the TNF family, or B lymphocyte stimulator (BLyS), see below) by monocytes, dendritic cells and salivary gland epithelial cells (Mavragani and Crow, 2010). T and B cell-attracting chemokines together with BAFF create a microenvironment supportive of B cell aggregation and differentiation, and local production of anti-SSA/SSB antibodies, with structural features remarkably similar to the germinal centre seen in lymph nodes (Ogawa et al, 2002; Salomonsson et al, 2003; Barone et al, 2005). B cells are overstimulated and produce excessive amounts of immunoglobulins and various autoantibodies. Peripheral blood and salivary gland B cell subset distribution is altered, leading to the constitution of ectopic germinal centres where autoreactive clones may escape tolerance checkpoints. Several B cell-specific cytokines, such as BAFF or FMS-like tyrosine kinase 3 ligand (Flt-3L), are instrumental in the occurrence of B cell dysfunction. Chronic and excessive stimulation of B cells may lead to the development of lymphoma in patients with SS.

In summary, a plausible pathophysiological scenario that might account for the complex immunopathology seen in SS would implicate a genetically determined exaggerated innate immune response against inappropriately overexpressed endogenous or exogenous danger signals. More specifically, transient or persistent infection of the epithelial cells by a putative virus may lead to genetically determined exaggerated induction of type I IFN production (Mariette and Gottenberg, 2010; Wahren-Herlenius and Dörner, 2013) by locally recruited plasmacytoid dendritic cells. This can lead to further activation of epithelial salivary cells through upregulation of the major histocompatibility complex and costimulatory molecules and to apoptotic events resulting in exposure of autoantigens such as Ro/SSA and La/SSB and generation of disease-specific anti-Ro/SSA and La/SSB autoreactivities (Kyriakidis et al, 2014). Recent data suggest that the glandular dysfunction may involve inhibitory operating mechanisms in the secretory process, including inhibition of neurotransmitter release by cytokines (interleukin 1, TNF α) (Zoukhri and Kublin, 2001), enhanced breakdown of acetylcholine by increased levels of cholinesterase in primary SS (Dawson et al, 2005), blockade of M3 receptors by antimuscarinic autoantibodies (Lee et al, 2013; Sumida et al, 2014), altered production and intracellular calcium mobilisation and altered fluid movement due to abnormal distribution of aquaporins.

4 Clinical findings

4.1 Signs and symptoms

4.1.1 Sicca features

Sicca features are symptoms that usually receive little attention and may be considered trivial by both doctor and patient. They progress slowly in time, and often patients do not consult timely at symptoms onset due to lack of awareness. Not all patients present the whole sicca spectrum, and likewise, sicca symptoms intensity may vary from patient to patient. Although often elusive, an early, accurate diagnosis of SS can help prevent, or ensure timely treatment of, many of the complications associated with chronic/severe dryness.

- **Dry mouth.** The subjective feeling of oral dryness is a key feature in the diagnosis of SS, occurring in >95% of patients. Other oral symptoms may include soreness, adherence of food to the mucosa and dysphagia, with subjective difficulty in swallowing (more common to solid food than liquids). Reduced salivary volume interferes with basic functions such as speaking or eating. The lack of salivary antimicrobial functions may accelerate local infection, tooth decay and periodontal disease. Xerostomia can lead to difficulty with dentures and the need for expensive dental restoration, particularly in elderly patients. Various oral signs may be seen in patients with SS. In the early stages, the mouth may appear moist, but as the disease progresses the usual pooling of saliva in the floor of the mouth disappears. Typically the surface of the tongue becomes red and lobulated, with partial or complete depapillation (figure 2). In advanced disease, the oral mucosa appears dry and glazed and tends to form fine wrinkles. Angular cheilitis, erythematous changes of the hard palate and a red tongue with atrophic papillae strongly suggest Candida infection.
- **Dry eyes.** The subjective feeling of ocular dryness produces sensations of itching, grittiness, soreness and dryness, although the eyes might look normal. Other ocular complaints include photosensitivity, erythema, eye fatigue or decreased visual acuity. Environmental irritants such as smoke, wind, air conditioning and low humidity may exacerbate ocular symptoms. Diminished tear secretion may lead to chronic irritation and destruction of corneal and bulbar conjunctival epithelium (keratoconjunctivitis sicca). Tears also have inherent antimicrobial activity and patients with SS are more susceptible to ocular infections, such as blepharitis, bacterial keratitis and conjunctivitis. Severe ocular complications may include corneal ulceration, vascularisation and opacification.
- **Other dryness.** Reduction or absence of respiratory tract glandular secretions can lead to dryness of the nose, throat and trachea, resulting in persistent hoarseness and chronic, non-productive cough (Ramos-Casals et al, 2009). Involvement of the exocrine glands of the skin leads to cutaneous dryness with pruritus. In female patients with SS, dryness of the vagina and vulva may result in dyspareunia, pruritus urinary urgency dysuria and recurrent urinary tract infection, affecting their quality of life.

Figure 2 Oral dryness and red tongue in a patient with primary Sjögren's syndrome. (Source: CRI (Club Rhumatismes et Inflammation), <http://www.cri-net.com>)

4.1.2 Glandular swelling

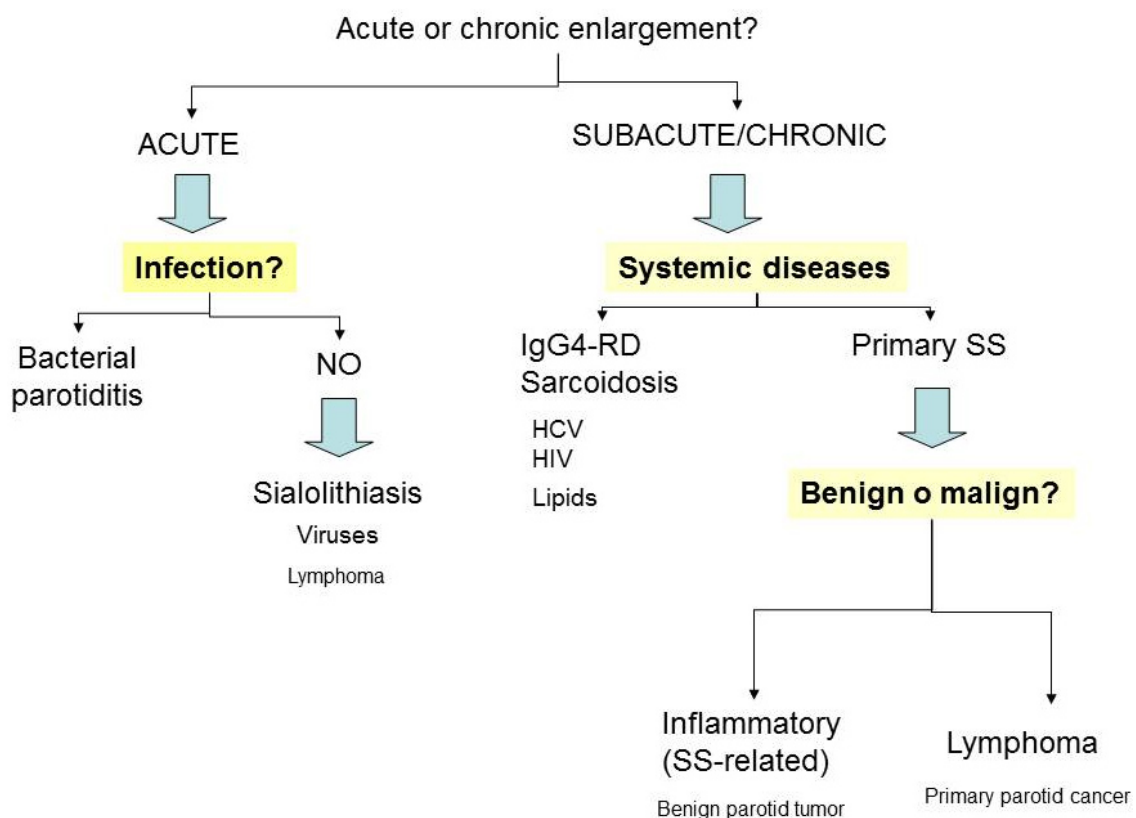

Chronic or episodic swelling of the major salivary glands is reported in 10–20% of patients and may start unilaterally, but often becomes bilateral (figure 3), affecting mainly the parotid glands but also the submandibular and sublingual glands. However, isolated submandibular gland enlargement is an atypical finding in SS that should make one consider other disorders, principally IgG4-RD (see online in-depth discussion). Differential diagnosis of unilateral salivary gland enlargement should include lymphoma, lithiasis and infections.

Figure 3 Bilateral parotid enlargement. Patient consent obtained. (Source: CRI (Club Rhumatismes et Inflammation), <http://www.cri-net.com>)

The course of glandular enlargement in SS varies from patient to patient. Enlarged salivary glands are usually bilateral, firm to palpation, either symmetrical or asymmetrical in size and have minimal symptoms. Enlargement can be episodic, with gradual waxing and waning, or chronic, with gradual progression over months or years. Although nearly 90% of patients with primary SS present inflammatory, benign parotid enlargement, B cell lymphoma should be always suspected, especially in patients with persistent enlargement. A rapid increase in the size of an enlarged gland associated with symptoms and signs of acute inflammation suggests a superimposed bacterial sialoadenitis and calls for systemic antibiotic treatment (figure 4).

Figure 4 Differential diagnosis of parotid enlargement. HCV, hepatitis C virus; HIV, human immune deficiency virus; IgG4-RD, IgG4-related disease; SS, Sjögren's syndrome.

4.1.3 General symptomatology

Patients with primary SS often present with general symptoms, which may have a much greater effect on the quality of life than sicca features. Low-grade, self-limiting fevers may occur in SS, usually in young patients with marked hypergammaglobulinaemia and positive immunological markers. Fatigue, generalised pain, fibromyalgia, and weakness are among the most debilitating clinical features of primary SS (Ng and Bowman, 2010*; Westhoff et al, 2012). Other non-specific symptoms closely associated with fatigue are sleep disturbances, anxiety and depression, with a prevalence according to recent studies of nearly 15%, 20% and 40% of patients with primary SS, respectively (Theander et al, 2010; Segal, 2012; Westhoff et al, 2012). Chronic pain is often associated with polyarthralgia/myalgia, which is reported by more than 50% of patients. Careful

assessment is essential, as this set of symptoms is also characteristic of other conditions (menopause, hypothyroidism, neoplasia, primary depression and, above all, fibromyalgia). The environment plays a key role in exacerbating these symptoms.

4.1.4 Organ-specific signs and symptoms

Patients may develop a large number of organ-specific signs and symptoms, either at presentation or during evolution of the disease, detailed as follows.

4.2 Systemic involvement

A long list of extra glandular features, including all the main organs and systems, is reported in patients with primary SS, the majority of whom are characterised by a 'Janus-faced' pattern of involvement (figure 5; table 1).

Figure 5 The 'Janus-faced' pattern of systemic involvement in primary Sjögren's syndrome.

Table 1 Major systemic manifestations of Sjögren's syndrome: percentage of overt clinical involvement in different large case series (Adapted from Ramos-Casals et al, BMJ 2012b;344:e3821*)

Organ	Manifestation
Skin	Purpura (10–15%) often related to cryoglobulinaemia Annular erythema (photosensitive erythematous lesions with indurated borders; 5–10%)
Joints	Non-erosive symmetrical arthritis (15–30%)
Lungs	Chronic obstructive lung disease (10%) Bronchiectasis (8%) Interstitial lung disease (5%)
Cardiovascular	Raynaud's phenomenon (18–37%) Pericarditis (<5%) Symptoms of autonomic dysfunction
Liver	Primary biliary cirrhosis (3–8%) Autoimmune hepatitis (<5%)
Pancreas	Recurrent pancreatitis (<5%)
Nephro-urological	Renal tubular acidosis (11%) Glomerulonephritis (<5%) Interstitial cystitis (<5%) Nephrolithiasis (<5%)
Peripheral nerves	Mixed polyneuropathy (5–10%) Pure sensory neuronopathy (5%) Mononeuritis multiplex (5%) Small-fibre neuropathy* (<5%) Myoclonus
Central nervous system	White matter lesions (MS-like disease) (<5%) Cranial nerve involvement (V, VIII and VII) (7%) Myelitis (<5%)
Thyroid	Autoimmune thyroiditis (14–33%)
Haematological	Autoimmune haemolytic anaemia (<5%) Severe thrombocytopenia <10 000/mm ³ (<5%) B cell lymphoma (5–10%)

**Patients with small-fibre neuropathy often present with painful burning dysaesthesia of the distal limbs. Because electromyographic studies may be normal, a skin biopsy often confirms the diagnosis. MS, multiple sclerosis.*

4.2.1 Joint and muscular involvement

Joint involvement (including either arthralgia or arthritis) was reported in 53% of patients included in retrospective/cross-sectional studies. The arthropathy is usually symmetrical, non-erosive and intermittent. The most commonly affected joints are the knees, wrists, interphalangeal and metacarpophalangeal joints (Fauchais et al, 2010). Joint deformity is rare, except when associated with RA or SS-related Jaccoud arthropathy.

A mild inflammatory myopathy has been reported in 2-47% of SS patients, being either subclinical or characterized by the insidious onset of proximal muscles weakness. Inclusion body myositis has been reported in rare cases and should be suspected in patients with muscles weakness and relatively low muscles enzymes elevation (Kanellopoulos et al, 2002) .

4.2.2 Skin

The main cutaneous manifestation in patients with primary SS is xerosis, present in 23-67%. It is characterized by dry, scaly skin, affecting mainly the lower extremities, and patients complain of pruritus. Hyperpigmented lesion may arise secondary to scratched skin. However, a wide spectrum of cutaneous lesions may be seen, the most common of which is a small-vessel vasculitis (Ramos-Casals et al, 2004a).

Vasculitis is reported in 10% of patients with primary SS included in retrospective studies, overwhelmingly presenting with cutaneous purpura (88%) (figure 6), with other cutaneous lesions such as nodules, digital lesions or maculopapular rash being rarely reported; cutaneous ulcers are reported in 8% of patients. Cryoglobulins are positive in one-third of cases and vasculitis is confirmed by biopsy in nearly half; 90% disclose leukocytoclastic vasculitis.

Figure 6 Cutaneous purpura.

Patients with primary SS may also present with non-vasculitic cutaneous lesions. Some patients with anti-Ro/SSA antibodies may present with polycyclic, photosensitive cutaneous lesions (figure 7), clinically identical to the so-called annular erythema (AE) described in Asian patients with SS and subacute cutaneous lupus. Recently, AE was reported as one of the most common cutaneous lesions found in European patients (Brito-Zerón et al, 2014). Subacute cutaneous lupus (idiopathic, drug-induced or related to SLE), AE and neonatal cutaneous lupus should be considered as a clinical spectrum of the same immune-mediated disease, which may have a common pathogenic basis, mainly related to anti-Ro antibodies.

Figure 7 Annular erythema.

Other skin lesions are erythema nodosum, livedo reticularis, lichen planus, cutaneous amyloidosis, vitiligo, eyelid dermatitis and angular cheilitis. Some lesions may arise due to treatment such as the hyperpigmentation seen in patients receiving hydroxychloroquine.

Figure 8 a. Cutaneous amyloidosis

Figure 8 b. Cutaneous amyloidosis histopathology

Figure 9 a. Hydroxychloroquine hyperpigmentation

Figure 9 b. Hydroxychloroquine hyperpigmentation histopathology

4.2.3 Lungs

Overall analysis of studies including unselected patients with SS found pulmonary involvement in 16%; one study focused on bronchial involvement and found bronchiectasis in 8% of patients. Clinical features included dyspnoea (62%), cough (54%), sputum/rales (14%), chest pain (5%) and fever (2%).

Two types of pulmonary involvement are predominant in primary SS (bronchial and interstitial), although most investigators have reported a predominance of bronchial/bronchiolar involvement rather than pulmonary fibrosis; the main underlying pathology in these patients is peribronchial infiltrates that leads to small airway disease (Papiris et al, 1999). CT findings found bronchiectasis/bronchiolar abnormalities (50%) and ground-glass opacities/interstitial changes (49%) to be the most common abnormalities. The most common histopathological diagnoses were non-specific interstitial pneumonia (NSIP) (45%), bronchiolitis (25%), usual interstitial pneumonia (UIP) (16%) and lymphocytic interstitial pneumonia (LIP) (figure 8) (15%). LIP has a strong association with primary SS, it is described as lymphoplasmocytic infiltrates within the interstitium, often forming nodular lymphoid aggregates, and lymphocytes within the alveolar spaces. These patients commonly also present polyclonal or monoclonal gammopathy.

Figure 8 Lymphocytic interstitial pneumonia in a 33-year-old woman with primary Sjögren's syndrome.

The typical symptoms of patients with bronchial or bronchiolar disease are cough, dyspnoea and recurrent respiratory infections (Soto-Cardenas et al, 2010). The classic pulmonary function test manifestation of this disease complication is a decreased maximal expiratory flow at 25% of vital capacity and a reduced diffusing capacity for carbon monoxide. Chest radiographs in these individuals are usually normal or show an ill-defined pattern of infiltrates that suggests interstitial lung disease (Ramos-Casals et al, 2009).

Cystic lung disease is a relatively common condition in SS. It has been reported in 15% of patients with chest imaging, being in occasions not evident in plain radiographs. In CT scans it has been observed in 30% of the patients. It does not progress in serial radiologic or function tests follow-up. In the absence of other radiographic findings it may represent a direct manifestation of SS (Martinez-Balzano, et al. 2016*

SS-related pulmonary disease is clearly associated with a poorer quality of life and shorter survival, with a two- to four-fold increase in the risk of death (Nannini et al, 2013; Palm et al, 2013) compared with patients without pulmonary disease. Enomoto et al (2013) identified PaCO₂, the extent of reticular abnormality and the severity of fibroblastic foci as the main baseline factors associated with death, while the histopathological patterns (UIP vs NSIP) had no influence in mortality.

4.2.4 Cardiovascular features

Raynaud's phenomenon, with a prevalence of 10–20%, is probably the most common vascular feature seen in primary SS and can appear before sicca symptomatology (García-Carrasco et al, 2002). The clinical course of Raynaud's phenomenon in primary SS is milder than in other systemic autoimmune diseases, such as SSc. Vascular complications (eg, digital loss, digital pulp pitting or fingertip infarctions) are uncommon, and pharmacological interventions are required in only 40% of cases. Capillaroscopic findings are long, thin capillaries with no avascular areas or ectasia.

Cardiac involvement is rarely seen, with pericardial effusions (usually mild and asymptomatic) being the most common feature (Vassiliou et al, 2008). Persistent pericarditis with signs of serositis, should raise the suspicion of another autoimmune disease (i.e., RA or SLE).

Several studies have reported autonomic cardiovascular disturbances, including orthostatic intolerance, secretomotor dysfunction, male sexual dysfunction, urinary dysfunction, gastroparesis, pupillomotor dysfunction, vasomotor dysfunction or sleep disorders (Ng et al, 2012).

Congenital heart block may develop in babies from anti-RO positive pregnant woman.

Other studies have reported a prevalence of pulmonary arterial hypertension in primary SS of 22% (Vassiliou et al, 2008). It should be suspected in patients with primary SS presenting with unexplained dyspnoea and normal chest radiography (Launay et al, 2007); associated SSc should always be investigated in these patients.

4.2.5 Gut

Gastrointestinal involvement may include altered oesophageal motility (dysphagia), chronic gastritis, and less frequently, malabsorption. *Helicobacter pylori* infection should be excluded in patients with gastritis, owing to the close association with gastric mucosa-associated lymphoid tissue lymphoma.

Liver function tests may be abnormal in 10–20% of patients with primary SS. After exclusion of potentially hepatotoxic drugs and steatohepatitis, the main causes are associated diseases, including chronic viral infections (mainly HCV infection) and associated organ-specific diseases (primary biliary cirrhosis and, less frequently, type 1 autoimmune hepatitis) (Ramos-Casals et al, 2006) (figure 9).

Celiac disease may be more prevalent in SS than compared to the general population.

Pancreatic involvement, usually asymptomatic, is demonstrated by altered pancreatic enzymes. Some patients may present with chronic pancreatitis, although investigation of a possible IgG4-RD should be mandatory in all patients with SS diagnosed with autoimmune pancreatitis or with autoimmune or sclerosing cholangitis (Stone et al, 2012; Mavragani et al, 2014).

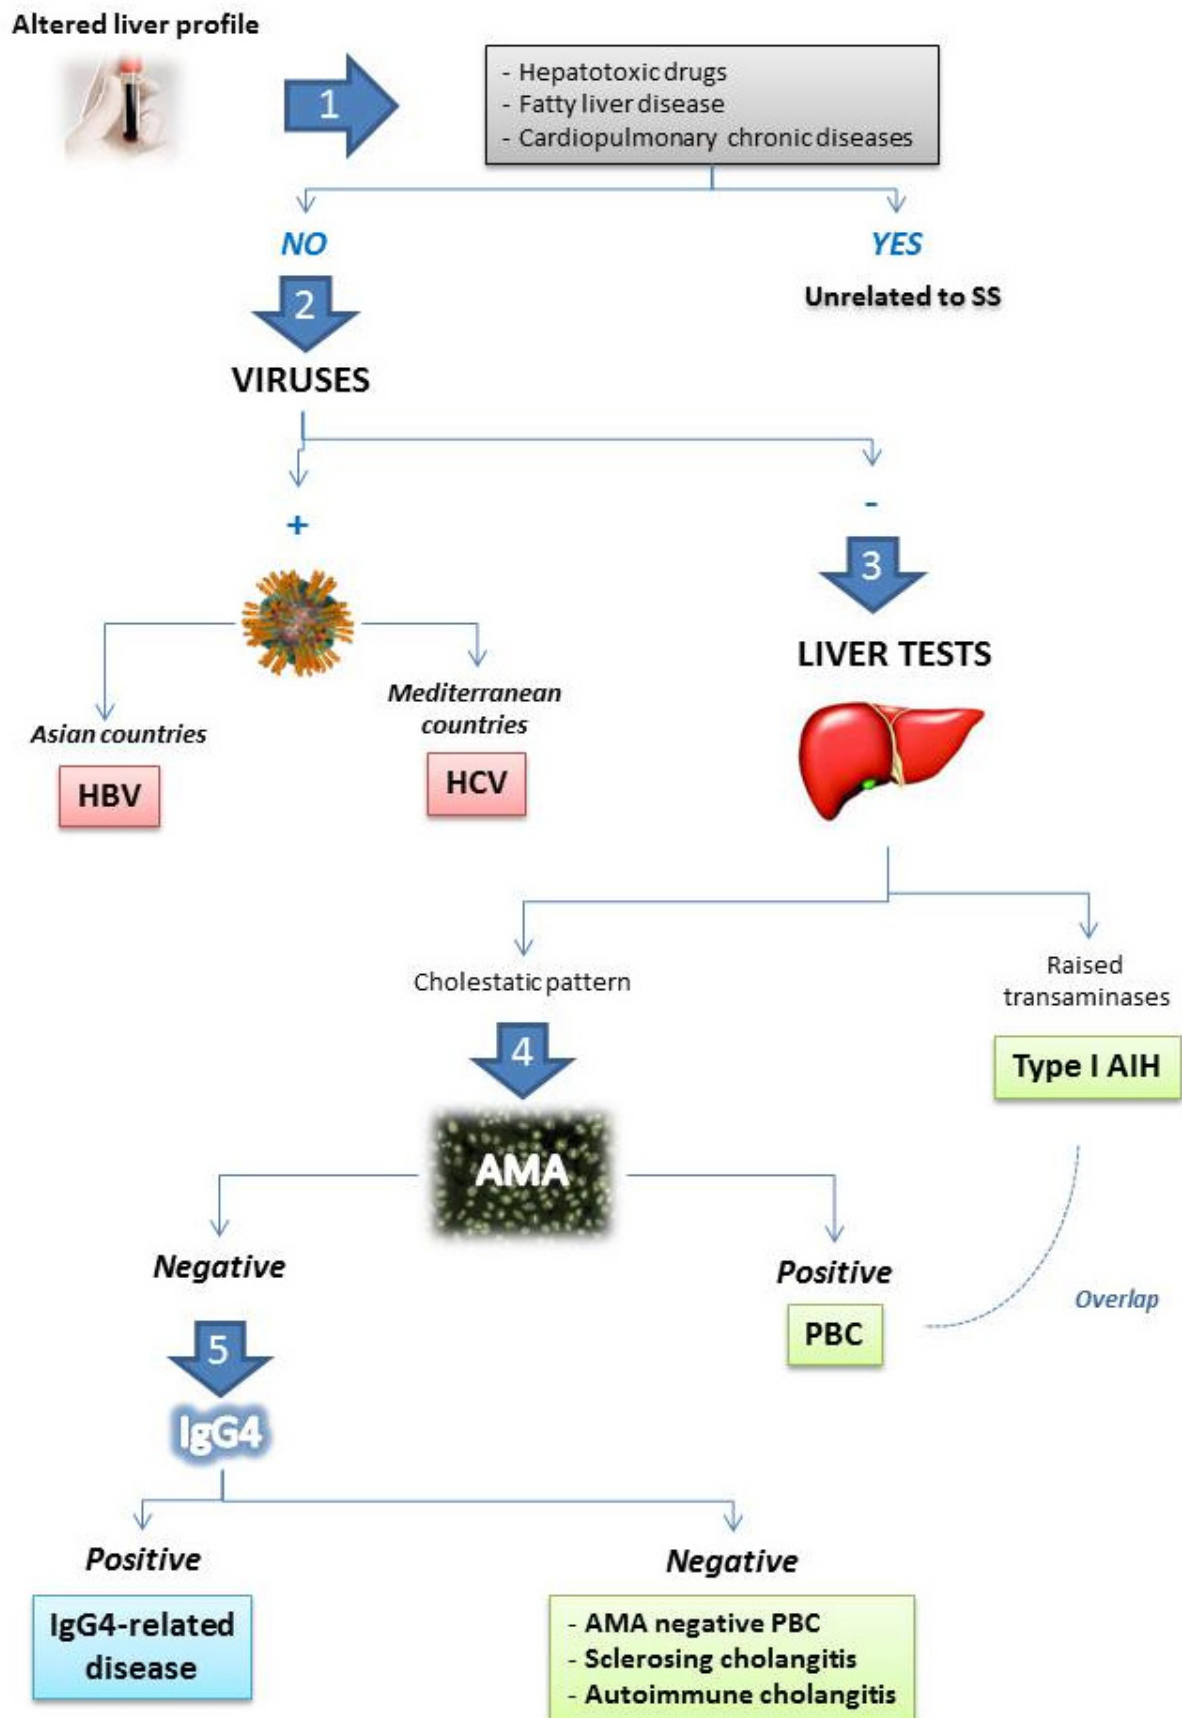

4.2.6 Nephro-urological and gynaecological involvement

Renal involvement is found in 5% of the nearly 2000 patients included in the largest reported series; the two types of renal involvement described are tubulointerstitial renal disease and glomerulonephritis.

Tubulointerstitial nephritis can be an early manifestation of SS and is caused by type I renal tubular acidosis (distal). The diagnosis is based on a persistent urine pH >5.3 even in the presence of a metabolic acidosis induced by NH₄Cl loading. Renal tubular acidosis may be diagnosed by two clinical features in two-thirds of cases, and by asymptomatic laboratory findings (mainly mild renal failure and/or proteinuria) in the remaining cases. Of symptomatic patients, the main feature (70%) is hypokalaemic weakness/paralysis (some with respiratory failure). Other clinical presentations may include nephrolithiasis and radiological nephrocalcinosis; there are some reported cases of osteomalacia (some with pathological fractures) and diabetes insipidus; renal failure was reported in 24% of patients. Renal biopsy was carried out in nearly half of the cases and disclosed tubulointerstitial nephritis in more than 90% of biopsies. Anti-SSA/SSB antibodies are frequent in tubulointerstitial nephritis and are associated with worse prognosis.

Glomerulonephritis, usually membranous and membranoproliferative, appears late in the course of the disease. The clinical presentation is often indolent. However, patients may present oedema/nephrotic syndrome, proteinuria, haematuria and renal failure. Patients with glomerulonephritis present with cryoglobulins, usually type II (mixed monoclonal, containing an IgMk monoclonal rheumatoid factor). Patients with glomerulonephritis have high rates of adverse outcomes, especially those with cryoglobulinaemia-mediated glomerular damage, while interstitial nephritis has a better prognosis. (Goules et al, 2013)

Figure 9 Differential diagnosis of liver involvement in patients with primary Sjögren's syndrome. AIH, autoimmune hepatitis; AMA, antimitochondrial antibodies; HBV, hepatitis B virus; HCV, hepatitis C virus; PBC, primary biliary cirrhosis; SS, Sjögren's syndrome.

Finally, interstitial cystitis, sometimes with severe symptoms, has been identified as a new extra glandular SS feature (Leppilahti et al, 2003). The clinical presentation may include a chronic history of pain/discomfort in the pelvic area and/or perineal pain accompanied by urinary urgency, frequency, dysuria and nocturia. These symptoms have been reported to be more frequent in SS patients compared to the general population (20 fold increase).

Gynaecologic manifestations include vulvovaginal dryness, dyspareunia, pruritus and frequent yeast infections. Moreover, anti-ovarian antibodies (AOA) occur frequently in patients with SS. High OAO may be an indication of Oophoritis and a possible cause of premature menopause.

4.2.7 *Peripheral neuropathy*

Peripheral neuropathy has been reported in 1.8% (Pavlakakis et al, 2011) to 10% of patients with primary SS undergoing electrodiagnostic testing (Brito-Zerón et al, 2013). The clinical course of the different types of peripheral neuropathies differs:

- Sensory or sensorimotor axonal polyneuropathy is the most common type of neuropathy and has the lowest frequency of SS-related immunological markers.
- Multiplex mononeuropathy is predominantly diagnosed in patients with a profile of 'high systemic activity' and has the poorest survival rate, and
- Pure sensory neuropathy is the most disabling in the long term and has the most discouraging therapeutic management (Brito-Zerón et al, 2013; Jamilloux et al, 2014). It is recognised as a typical neurological complication of primary SS, caused by damage to the sensory neurons of the dorsal root and gasserian ganglia. A recent study characterised 40 patients with primary SS diagnosed with sensory small-fibre neuropathy (Sene et al, 2013); these patients had an older age at diagnosis and a lower frequency of hypergammaglobulinaemia and autoantibodies. The diagnosis often relies on quantitative sensory testing and sural nerve biopsy, but skin biopsy is an increasingly useful technique for demonstrating a decrease in the density of epidermal nerve fibres (Chai et al, 2005; Gøransson et al, 2006). Patients with small-fibre neuropathy have normal nerve conduction studies, because the size of nerve fibres involved is below the resolution of conventional electrodiagnostic studies (Ramos-Casals et al, 2009). Sural nerve biopsy may show vascular or perivascular inflammation of small epineurial vessels (both arterioles and venules) and, in some cases, necrotizing vasculitis. The loss of myelinated nerve fibres is common and loss of small-diameter nerve fibres occurs. The histopathology of sensory ganglioneuronopathy consists of the loss of neuronal cell bodies and T cell infiltration.

Patients with SS may also present cranial nerve involvement, mainly of the trigeminal (V), vestibulocochlear (VIII) and facial (VII) cranial pairs. Trigeminal neuralgia is a common complication of primary SS, reported in

about 15% of patients with any kind of neuropathy. It is usually unilateral. The pain is distributed in the regions that are innervated by the branches of the trigeminal nerve (Ramos-Casals et al, 2009).

4.2.8 Central nervous system involvement

Severe organic central nervous system (CNS) involvement in patients with primary SS is extremely rare. However, some patients may present a wide spectrum of non-specific neurological manifestations that can be difficult to differentiate from other neurological diseases, including those frequently reported in non-autoimmune patients. A recent study found features such as pain, fibromyalgia, fatigue, headache and psychiatric/cognitive disorders in more than 70% of 120 patients with primary SS (Morreale et al, 2014), while Jamilloux et al (2014) found a sevenfold lower prevalence (10%) in 420 patients, including only neurological involvements confirmed by specific diagnostic tests. Tjensvoll et al (2013) confirmed the high frequency of headache in patients with primary SS (70%), likewise the prevalence in an age-sex matched control group was similar (60%).

The most frequently detected CNS feature in primary SS is asymptomatic white matter lesions in magnetic resonance studies. A recent study found that these lesions are overwhelmingly associated with concomitant cardiovascular risk factors, although isolated cases of patients with SS presenting with a multiple sclerosis (MS)-like disease (figure 10) were also reported (Akasbi et al, 2012).

Furthermore, cognitive dysfunction including memory loss and poor concentration are other manifestations. Patients frequently call this “brain fog”. Neurocognitive studies reveal a lower performance. These patients often suffer from depression. Further studies are needed to determine the relationship between depression and these cognitive impairment.

Some patients may develop aseptic meningitis or features of myelitis with or without optic neuritis, similar to ‘Devic's disease’.

Figure 10 Demyelinating central nervous system lesions in a patient with primary Sjögren's syndrome and multiple sclerosis-like disease.

The clinical approach to patients with primary SS with suspected CNS involvement requires diagnostic procedures to define the type of neurological involvement, and also the exclusion of processes not directly related to primary SS. These include the coexistence of other systemic autoimmune diseases (antiphospholipid syndrome, SLE and systemic vasculitis), the differential diagnosis from organ-specific autoimmune CNS disorders (MS, Devic's disease) and lymphoma of the CNS. Much more frequently, however, the clinician should consider non-autoimmune processes involving CNS in patients aged >50 years (cardiovascular disease, neurodegenerative processes).

4.2.9 Ear, nose and throat involvement

Although ear, nose, and throat involvement has been little studied in patients with primary SS, some studies have described sensorineural hearing loss in nearly 25% of patients with SS whose results were pooled from four studies (Ramos-Casals et al, 2005b). Associations with immunological parameters such as ANAa, antiphospholipid antibodies and anti-Ro/SSA or anti-La/SSB antibodies have been postulated but not proved. Sensorineural hearing loss in primary SS preferentially affects high-frequency hearing, but deficits often

remain subclinical (Boki et al, 2001). Retrocochlear disease and symptoms of vestibular dysfunction are not typical of SS (Ramos-Casals et al, 2009).

5 Diagnostic approach

5.1 Glandular functioning

5.1.1 Assessment of oral involvement

Several methods for assessing oral involvement have been proposed, including measurement of the salivary flow rate, ultrasonography, sialography or scintigraphy.

- Unstimulated whole sialometry ≤ 1.5 mL/15 min, or 0.1 mL/min is pathologically decreased. It is the easiest and less invasive exam to assess mouth dryness. Stimulated whole sialometry can also be performed 5 min after the unstimulated whole sialometry, using standardised paraffin chewing gums or lemon juice. Patients should be instructed to spit saliva into a graduated test tube every minute, with a quantity of <1.5 mL collected over a 15 min period; this has a sensitivity of 56% and a specificity of 81% for SS (Vitali et al, 2002*). These procedures are easy to perform at a physician's office during each visit.
- Parotid scintigraphy has greater sensitivity (80%) and specificity (86%) (Vitali et al, 1993) and classifies the grade of involvement of the major salivary glands into four grades, with severe involvement (grade IV) at diagnosis being prospectively associated with a higher risk of lymphoma and death (Ramos-Casals et al, 2010a). It is an expensive test and it is performed in referral centres.
- Ultrasonography is a non-invasive method that may provide useful information about the aetiology of parotid enlargements (Cornec et al, 2014a). Theander and Mandl (2013) recently evaluated the usefulness and prognostic value of a simplified salivary gland ultrasonography scoring system. This test has the potential to be included in the diagnostic/classification criteria of the disease (Goules and Tzioufas, 2014). It should be noted, however, that further validation, particularly against disease controls, is required (Tzioufas and Moutsopoulos, 2008). Typical findings include hypoechoic areas with convex borders in early stages, and hyperechoic bands, cysts and calcifications in more established disease. The sensibility for ultrasonography is around 55-66% and the specificity 93-98% depending on the different authors. There are ongoing studies on elastography that must be evaluated in the future.
- Magnetic resonance imaging (MRI): MRI of the parotid gland typically shows a nodular pattern, with multiple hypo and hyperintense areas of varying size. MRI correlates well with salivary gland biopsy.
- Sialography. Conventional x-ray sialography may show the so-called cherry blossom or snow flake pattern. The procedure is invasive and painful. It is a test that is not currently recommended.

5.1.2 Assessment of ocular involvement

There are several tests that evaluate the grade of ocular involvement. The most common is the Schirmer's test followed by corneal staining using colourants (Rose Bengal, fluorescein) (figure 11) for slit lamp examination to detect conjunctival epithelium destroyed by desiccation.

- Schirmer's test evaluates tear production. A filter paper is placed between the middle and lateral fornix of each eye. The patient is then asked to close the eyes during 5 minutes. The extent of tear wicking is recorded and is considered normal when greater than 5mm.
- Rose Bengal scoring involves placement of 25 mL of Rose Bengal solution in the inferior fornix of each eye and asking the patient to blink twice. Slit lamp examination detects destroyed conjunctival epithelium due to desiccation. The van Bijsterveld score expresses the results of this test.
- The Lissamine green test evaluates conjunctiva structural damage and has widely replaced the painful Rose Bengal test. The conjunctiva are stained with green colourant. If the epithelium is damaged, the conjunctivas are stained. Each area of the eye (nasal, central, temporal) is scored semi quantitatively from 0 to 3, depending on the extent of surface staining. The sum of the different scores constitutes the van Bijsterveld score (figure 12), which ranks from 0 to 9 for each eye. It is considered as a diagnostic criterion if the score is ≥ 4 in both eyes.
- Ocular staining score (OSS) implies the use of fluorescein and lissamine green dye. First, fluorescein is instilled in each eye. Then a drop of lissamine green dye is instilled in each anaesthetised eye. The number of dots of staining in the cornea and in the nasal and temporal portions of the conjunctiva are graded. The sum of the fluorescein score for the cornea and the lissamine green scores for the nasal and temporal conjunctiva yields the total OSS. This score is the one used in the new set of classification criteria. (Witcher 2010)
- Tear break-up time. It evaluates the stability of the lachrymal film. Normally, the tear film does not break for 10 seconds, at least. This test is not included in the 2002 American-European classification criteria.

Figure 11 Fluorescein corneal staining.

Figure 12 Queratoconjunctivitis sicca: the van Bijsterveld score.

5.2 Laboratory findings

The most common analytical features in routine laboratory tests are cytopenia, raised erythrocyte sedimentation rate (ESR) and hypergammaglobulinaemia (20–30%) (table 2).

Table 2 Laboratory evaluation in Sjögren's syndrome

Test	Typical result
Complete blood cell count	Normochromic, normocytic anaemia. Isolated cases of haemolytic anaemia Mild leukopenia ($3-4 \times 10^9/L$); lymphopenia, neutropenia Mild thrombocytopenia ($80-150 \times 10^9/L$)
Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)	Raised ESR (>50 mm/h) in 20–30% of cases, especially in patients with hypergammaglobulinaemia Normal values of CRP
Serum protein	Hypergammaglobulinaemia Monoclonal band
Liver function tests	Raised transaminases (associated with hepatitis C virus or autoimmune hepatitis) Raised alkaline phosphatase and/or bilirubin (associated with primary biliary cirrhosis)
Electrolytes and urine analysis	Proteinuria (glomerulonephritis) Hyposthenuria, low plasma bicarbonate and low blood pH (renal tubular acidosis)
Antinuclear antibody test	Positive in $>80\%$
Rheumatoid factor	Positive in 40–50% of patients, often leading to diagnostic confusion with rheumatoid arthritis
Anti-extractable nuclear antigen antibodies	Positive anti-Ro/SSA (30–70%) and anti-La/SSB (25–40%)
Complement (C3, C4 and CH50)	Complement levels are decreased in 10–20% of patients (predictive factor for future lymphoma development)
Cryoglobulins	Present in 10–20% of patients (predictive factor for future lymphoma development)
Other autoantibodies	Antimitochondrial antibodies (associated with primary biliary cirrhosis) Antithyroid antibodies (associated with thyroiditis Hashimoto's disease) Anti-dsDNA (associated with systemic lupus erythematosus) Anticentromere (associated with a limited form of systemic sclerosis)

- Cytopenias are usually asymptomatic. The most frequent are normocytic anaemia, leukopenia and thrombocytopenia; the most common abnormality is lymphopenia, closely followed by neutropenia. Cytopenias are found more commonly in patients with positive immunological markers.
- Raised ESR levels correlate closely with the percentage of circulating gamma globulins (hypergammaglobulinaemia), while serum C-reactive protein levels are usually normal. Greatly increased serum C-reactive protein levels in a patient with primary SS should raise the suspicion of an infection. Clinicians who observe high ESRs in patients with SS should therefore not leap to conclusions about occult infections, subclinical malignancies, or the presence of systemic vasculitis as potential causes of ESR elevations: it may simply be the SS itself. In such patients, the C-reactive protein is usually normal (Ramos-Casals et al, 2009).

- **Hypergammaglobulinaemia.** Polyclonal hypergammaglobulinaemia is one of the most characteristic laboratory abnormalities found in primary SS. It reflects the polyclonal B cell activation implicated in the pathogenesis of the disease and provides useful analytical data that may strengthen the diagnosis of primary SS in a patient with sicca syndrome. The prevalence of hypergammaglobulinaemia varies according to the classification criteria and the parameter used to define it, ranging from 22% to 42%. Hypergammaglobulinaemia is closely associated with the key immunological markers of SS (RF, anti-Ro/SSA and anti-La/SSB) (Brito-Zerón et al, 2012*).
- Hypogammaglobulinemia is less common than hypergammaglobulinemia and may develop as a predictor sign of lymphoma.

5.3 Immunological studies

The proven diagnosis of SS requires documentation of sicca symptoms and objective evidence of dry eyes and mouth, and also analytical evidence of autoimmunity, as sicca syndrome has many causes. Autoantibodies may appear several years before the disease diagnosis, as recently shown by Jonsson et al (2013*). Although dryness is the first symptom to appear in most patients, a large number of non-sicca features may appear before the sicca symptoms arise (box 3), including extra glandular manifestations and a specific condition in which the disease presents 'indirectly': with congenital heart block in the baby of an asymptomatic pregnant women carrying anti-Ro antibodies.

Box 3 Non-sicca manifestations suggestive of Sjögren's syndrome se puede agregar aqui cognitive dysfunction ? generalized pain ?

Clinical features

- Chronic fatigue
- Fever of unknown origin
- Leucocytoclastic vasculitis
- Parotid or submandibular gland swelling
- Raynaud's phenomenon
- Peripheral neuropathy
- Clinical features of renal tubular acidosis of unknown origin
- Cough dyspnoea dysphagia
- Mother of a baby born with congenital heart block

Analytical features

- Raised erythrocyte sedimentation rate
- Hypergammaglobulinaemia
- Leukopenia and thrombocytopenia
- Serum and/or urine monoclonal band
- Positive antinuclear antibodies or rheumatoid factor in an asymptomatic patient

The main immunological markers found in primary SS are ANAs, anti-Ro/SSA or anti-La/SSB antibodies, RF, hypocomplementaemia and cryoglobulins (table 2).

- ANA and RF. Antinuclear antibodies are the most frequently detected antibodies in primary SS (in >80% of cases). Patients with rheumatoid factor positivity show a higher frequency of extra glandular and immunological features including articular involvement, cutaneous vasculitis, ANA and anti-Ro/SSA. The results in larger studies support a key role of rheumatoid factor in the diagnosis of primary SS because this immunological marker has an independent association with most of the main clinical and immunological features of the disease. Thus, rheumatoid factor is a useful immunological test for the diagnosis of some subsets of patients with primary SS, such as those with extra glandular manifestations or with circulating cryoglobulins (Retamozo et al, 2012a).
- Anti-Ro/SSA and La/SSB antibodies are detected in 30–70% of patients and are closely associated with extra glandular features, especially with cutaneous lesions, neurological features, congenital heart block, cytopenias and vasculitis. They are also associated with the intensity of lymphocytic infiltrates in the salivary glands (Routsias and Tzioufas, 2010). Their prevalence may vary widely according to the method of detection (ELISA, double immunodiffusion, western blot), due to their varying capacity to recognise antibodies against the Ro52 and Ro60 subunits. Our group found that 12% of our patients who tested negative for the standard detection of anti-Ro/SSA antibodies were positive for anti-Ro52 antibodies (Retamozo et al, 2012a), while Mekinian et al (2013) found that immunoblot identified anti-Ro52/60 antibodies in >20% of patients with negative Ro/SSA. In addition, anti-Ro60 antibodies are more easily detected if a native antigen is used (95% vs 54% using recombinant antigens) (Gordon et al, 2004). In patients with a high clinical suspicion of primary SS and negative results for the standard determination of anti-Ro/SSA antibodies (or even those negative for antinuclear antibodies), specific detection of anti-Ro52/60 antibodies using the most appropriate techniques is recommended.
- New early Sjögren tests include Salivary Protein SP-1, carbonic Anhydrase-6 (CA6) and parotid Specific Protein (PSP). These tests require more studies before they are accepted worldwide.
- Cryoglobulins. Nearly 10% of cases, with primary SS may present with circulating cryoglobulins, overwhelmingly mixed (Ramos-Casals et al, 2012c). The clinical significance of cryoglobulinaemia in primary SS is threefold. First, cryoglobulins are associated with a higher prevalence of extra glandular disease. Second, patients with cryoglobulinaemia are at a higher risk of B cell lymphoma than are those who do not have cryoglobulins (Tzioufas et al, 1996). Third, there is a close association between cryoglobulinaemia and life-threatening vasculitis (Retamozo et al, 2012).
- Low complement levels. In patients with primary SS, hypocomplementaemia is found in 10–25% of patients. Hypocomplementaemia is closely associated with the two main adverse outcomes of primary SS (lymphoma development and death) (Skopouli et al, 2000, Ramos-Casals et al, 2005a).
- Monoclonal immunoglobulins. The presence of monoclonal immunoglobulins in the sera and urine of patients with primary SS has been well known since the 1960s (Moutsopoulos et al, 1983; Moutsopoulos et al, 1985). In >20% of patients it may appear as monoclonal gammopathy of undetermined significance

(MGUS) (Brito-Zerón et al, 2012*); these studies have led to the inclusion of MGUS as a key marker of disease activity in the recently proposed European SS Disease Activity Score (ESSDAI) (Seror et al, 2010).

5.4 Histopathology

Minor salivary gland biopsy remains a highly specific test for the diagnosis of SS (Guellec et al, 2013), although it is an invasive technique, it is safe and associated with few adverse local effects (Caporali et al, 2008). Focal lymphocytic sialadenitis (figure 13), defined as multiple, dense aggregates of ≥ 50 lymphocytes in perivascular or periductal areas in the majority of sampled glands, is the characteristic histopathological feature of SS. The key requirements for a correct histological evaluation are an adequate number of informative lobules (at least four) and the determination of an average focus score (a focus is a cluster of at least 50 lymphocytes). However, non-specific sialadenitis is quite common in-- samples of minor salivary glands in healthy control populations. Although sialadenitis is the key histopathological feature of SS, this finding in the absence of symptoms and markers suggestive of SS should be interpreted with caution. Minor salivary gland biopsy may be also useful in resolving the differential diagnosis of patients with systemic diseases that infiltrate salivary glands and who also present with sicca symptoms (e.g., sarcoidosis, amyloidosis, IgG4-RD).

A positive lip biopsy is found in 66 to 90% of patients classified with SS according to the 2002 AECG criteria, resulting in an 80% sensitivity. Thus, it is not pathognomonic for SS, being also found in patients with rheumatoid arthritis, lupus, limited systemic sclerosis and in healthy individuals.

Figure 13 Focal lymphocytic sialadenitis. (Source: CRI (Club Rhumatismes et Inflammation, <http://www.cri-net.com>)

5.5 Classification criteria

At least 10 diagnostic/classification criteria for SS have been published since the 1960s. The 2002 AECG classification criteria for SS (Vitali et al, 2002*) were created to update the 1993 European Community Criteria for Classifying SS (Vitali et al, 1993) and were adopted by the scientific community worldwide. These criteria sought to correct problems with earlier criteria sets by requiring that evidence of an autoimmune process characteristic of SS should be included. The 2002 criteria stipulate that a positive anti-Ro/SSA or La/SSB antibody assay or a positive labial salivary gland biopsy is mandatory (box 4) (Vitali et al, 2002*) with a sensitivity of 93.5% and a specificity of 94%.

Box 4 2002 American–European classification criteria for Sjögren's syndrome

- 1. Ocular symptoms: a positive response to at least one of the following questions:**
 1. Have you had daily, persistent, troublesome dry eyes for more than 3 months?
 2. Do you have a recurrent sensation of sand or gravel in the eyes?
 3. Do you use tear substitutes more than three times a day?
- 2. Oral symptoms: a positive response to at least one of the following questions:**
 1. Have you had a daily feeling of dry mouth for more than 3 months?
 2. Have you had recurrently or persistently swollen salivary glands as an adult?
 3. Do you often drink liquids to help in swallowing dry food?
- 3. Ocular signs: objective evidence of ocular involvement defined as a positive result for at least one of the following two tests:**
 1. Schirmer test, performed without anaesthesia (5 mm in 5 min)
 2. Rose Bengal score or other ocular dye score (4 according to the van Bijsterveld scoring system)
- 4. Histopathology.** In minor salivary glands (obtained through normal-appearing mucosa), focal lymphocytic sialadenitis, evaluated by an expert histopathologist, with a focus score of 1, defined as a number of lymphocytic foci (which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes) per 4 mm² of glandular tissue
- 5. Salivary gland involvement: objective evidence of salivary gland involvement defined by a positive result for at least one of the following diagnostic tests:**
 1. Unstimulated whole salivary flow (1.5 mL in 15 min)
 2. Parotid sialography showing the presence of diffuse sialectasias (punctate, cavitary or destructive pattern), without evidence of obstruction in the major ducts
 3. Salivary scintigraphy showing delayed uptake, reduced concentration and/or delayed excretion of tracer
- 6. Antibodies to Ro/SSA or La/SSB antigens, or both**

Patients are classified as having primary SS when they fulfil four or more of the six classification criteria; either criterion 4 (salivary gland biopsy) or criterion 6 (anti-Ro/La antibodies) is mandatory.

In 2012, Shiboski et al, proposed a new set of classification criteria for SS on behalf of the American College of Rheumatology (ACR criteria). These differ from the AECG criteria in the exclusion of some features (sicca symptoms and diagnostic tests of salivary glands) and the modification of others (inclusion of a new ocular staining score and of ANA plus RF in the immunological criteria) (Vitali et al, 2013).

Recent studies have compared the two sets of criteria (ACR vs AECG). Cornec et al (2014b) found a moderate degree of agreement between the two sets, mainly due to differences in the ocular criteria, while Rasmussen et al (2014) found that 20% of the Oklahoma cohort fulfilled only one of the two sets of criteria, with 35 patients not classified as primary SS using the ACR criteria, despite having a positive biopsy or Ro/La antibodies. The ACR criteria more easily classified Ro/La-negative patients and those with early disease (Cornec et al, 2014b), while the AECG criteria were more specific (Rasmussen et al, 2014) and more easily classified patients with systemic disease. Quartuccio et al (2014a*) found a higher prevalence of glandular swelling and extra glandular involvement, and more frequent use of systemic treatments in patients fulfilling the AECG criteria. These findings suggest that a final agreement on classification criteria for primary SS is still necessary. This is a current endeavour, as a collaborative project between EULAR and ACR.

In 2016, a new set of classification criteria were presented for primary SS. These were developed and validated using approaches approved by ACR and EULAR. This new set of classification criteria are applicable to any patient with at least one symptom of ocular or oral dryness according to AECG questions, or suspicion of SS due to systemic features derived from the ESSDAI. Exclusion criteria are: history of head and neck radiation treatment, active HCV, AIDS, sarcoidosis, amyloidosis, graft versus host disease and IgG4 related disease. The new criteria differs from previous ones in that they are based on weighted sum of items derived from expert opinion and analyses of patient data. Furthermore, positive anti-SSB/La in the absence of anti-SSA/Ro is no longer considered a criteria. They include Schirmer's test and unstimulated whole saliva flow. The cut-off value for ocular staining score was raised to 5, and the van Bijsterveld score was added as an alternative to this. They removed ANA and RF as items. (Shiboski C et al. 2016*)

Box 5 2016 American College of Rheumatology–European League Against rheumatism classification criteria for primary Sjögren's syndrome

ITEM	WEIGHT/SCORE
Labial salivary gland with focal lymphocytic sialadenitis and focus score of ≥ 1 foci/4mm ²	3
Anti-SSA/Ro positive	3
Ocular staining score ≥ 5 (or van Bijsterveld score ≥ 4) in at least 1 eye	1
Schirmer's test ≤ 5 mm/5 minutes in at least 1 eye	1
Unstimulated whole saliva flow rate ≤ 0.1 ml/minute	1

Patients are classified as primary SS if they have a total score of ≥ 4 , derived from the sum of the weights of each positive item.

6 Differential diagnosis

The most common cause of sicca features is the chronic use of dry drugs (mainly antihypertensive, antihistamine and antidepressant agents) (box 6), especially in the elderly. After excluding this cause, three other main causes of sicca syndrome remain (box 7).

Tear and unstimulated saliva production decline with age, due to age-related histologic alterations in lacrimal and salivary glands. These patients lack of the typical histologic changes seen in SS, and anti-SSA/Ro and anti-SSB/La are in general negative.

Box 6 Drugs causing sicca syndrome

- Anticholinergic drugs (atropine, scopolamine)
- Sympathomimetic drugs (ephedrine)
- Benzodiazepines
- Selective serotonin reuptake inhibitors
- Tricyclic antidepressants
- Phenothiazines
- Antihistamines
- Nicotine
- Opioids
- α -1 Antagonists (terazosin and prazosin)
- α -2 Agonists (clonidine)
- β Blockers (atenolol, propranolol)
- Diuretics

Box 7 Diseases that may mimic Sjögren's syndrome

Other diseases infiltrating exocrine glands

- Granulomatous diseases (sarcoidosis and tuberculosis)
- Amyloidosis
- Neoplasias (lymphoma)
- IgG4-related disease
- Type V hyperlipidaemia

Other processes

- Graft-versus-host disease
- Eosinophilia-myalgia syndrome
- Radiation injury
- Medication-related dryness
- Diabetes mellitus
- Dehydration

1. *External or environmental factors*, including allergy/atopy, local infections, dehydration or irradiation may be a cause of mucosal dryness.
2. *Chronic viral infections* such as HCV or human immune deficiency virus, which may induce lymphocytic infiltration of exocrine glands. The aetiopathological and clinical significance of viral infection in patients with SS varies depends on the geographical area. In Japan, where human T cell lymphotropic virus type I (HTLV-I) is endemic, nearly 25% of patients with primary SS have HTLV-I infection (Nakamura et al, 2000). HTLV-I may be considered the viral counterpart in Asian countries of HCV in the Mediterranean region (Ramos-Casals et al, 2009).
3. *Some systemic diseases* may mimic the clinical picture of SS through infiltration of the exocrine glands by granulomas (sarcoidosis and tuberculosis), amyloid proteins (amyloidosis) or malignant cells (haematological neoplasia). A more recently recognised cause of salivary gland infiltration is IgG4-RD (see online in-depth discussion).

7 Outcome and prognosis

Primary SS usually progresses very slowly, with no rapid deterioration in salivary function or dramatic changes in sicca symptoms. The main exceptions to this benign course are the development of systemic manifestations and the high incidence of lymphoma.

7.1 Systemic activity

Systemic involvement plays a key role in the prognosis of primary SS. Three recent multicentre studies, including more than 2500 European patients, confirmed that primary SS is, undeniably, a systemic autoimmune disease (Seror et al, 2013; Baldini et al, 2014; Ramos-Casals et al, 2014).

Box 8 describes patients with poor prognosis.

Box 8. Poor prognostic factors

Severe parotid involvement
Vasculitis/purpura
Hypocomplementemia
Cryoglobulinaemia
Hypergammaglobulinaemia
Rheumatoid Factor
Germinal centres
Dendritic cells

EULAR has recently promoted an international collaboration between primary SS experts to develop consensus disease activity indexes. Two indexes have been developed: (i) a patient-administered questionnaire to assess subjective symptoms, the EULAR Sjögren's Syndrome Patients Reported Index (ESSPRI) and (ii) a systemic activity index to assess systemic complications, the EULAR Sjögren's Syndrome Disease Activity Index (ESSDAI).

Development of the ESSDAI (Seror et al, 2014*) by the EULAR task force on SS represents a step forward in the evaluation of systemic SS. The ESSDAI includes specific organ-by-organ definitions and allows homogeneous evaluation of systemic features in large series of patients.

In contrast, a large percentage of patients with primary SS have no systemic involvement, with a clinical pattern totally dominated by severe dryness, associated sometimes with fatigue and pain, which are not life-threatening but have a serious impact on the quality of life (Lendrem et al, 2013). Greater intensity of dryness, fatigue and pain seems to go in tandem with less systemic involvement and identification of immunological SS features. Physical impairment and pain do not always correlate with serologic positivity.

7.2 Lymphoma

Patients with primary SS are at higher risk of lymphoma than healthy people (10- to 44-fold) and patients with other autoimmune diseases (seven- and fourfold in patients with SLE and RA, respectively) (Zintzaras et al, 2005). The main series included 2–9% of patients diagnosed with lymphoma (Tzioufas and Voulgarelis, 2007; Ramos-Casals et al, 2012). The most recent studies have found similar figures, with a nine fold risk reported by Johnsen et al (2013) and a pooled 14-fold risk found in a recent meta-analysis by Liang et al (2013), with the prevalence of lymphoma estimated at 2%, 6% and 11% in three large series of patients with primary SS (Voulgarelis et al, 2012; Johnsen et al, 2013; Quartuccio et al, 2014b).

Lymphomas that develop in patients with primary SS are extra nodal in 80% of cases, with the most common site being the parotid glands (Voulgarelis et al, 1999). Persistently hard enlargement of the parotid gland or (much more rarely) of the lachrymal glands should alert the clinician of the possibility of a lymphoma. Lymphomas developing in SS may also occur in the gastrointestinal tract or lungs. Mucosa-associated lymphoid tissue lymphomas are the most common type, followed by marginal zone lymphomas. After years of slow progression, low-grade tumours in some patients may progress to rapidly growing, high-grade lymphomas.

Prospective studies have identified severe parotid involvement, purpura, splenomegaly, cryoglobulins, monoclonal band and hypocomplementaemia as risk factors for lymphoma (Tzioufas et al, 1996; Skopouli et al, 2000; Ioannidis et al, 2002*; Ramos-Casals et al, 2008). Also, raised levels of BAFF and $\beta 2$ microglobulin (Gottenberg et al, 2013b), leukopenia and anti-La antibodies (Quartuccio et al, 2014b), may serve as risk factors. Quartuccio et al (2014b) also reported that, in patients with parotid enlargement, only those presenting with these biomarkers had an increased risk of lymphoma.

Most interesting is the information provided by a labial salivary gland biopsy. Theander et al (2011) showed that the presence of ectopic germinal centre-like structures may predict lymphoma development in pSS, while in another study it was shown that the presence of macrophages and dendritic cells in the salivary gland biopsy specimen, as well as the cytokine interleukin 18, may also correlate with adverse predicting factors for lymphoma development (Manoussakis et al, 2007). These findings open new avenues for the definition of cellular and molecular biomarkers for adverse outcome of the disease, derived from the affected tissue.

7.3 How to follow-up and monitor?

We recommend a multidisciplinary approach follow-up guided by the rheumatologist. Patients with stable disease limited to mucosal surfaces may require only annual evaluation, while those with extra glandular manifestations should be evaluated every 6 months and those with end-organ damage every 3 months). However, the frequency of follow-up evaluations should be individualized according to each patient's needs. Routine physical examination should include evaluation of the mouth and eyes to treat sicca complains which

diminish the quality of life, exclude local complications and examination for peripheral lymphadenopathy and enlargement of parotid/submandibular glands, the liver and the spleen. Yearly laboratory tests should include full blood count, erythrocyte sedimentation rate (ESR) and renal and liver function tests. Immunological tests are not necessary in routine follow-up, with two exceptions: patients with markers (low complement levels, mixed cryoglobulinaemia, monoclonal gammopathy) associated with a poor prognosis, or when there is clinical suspicion of a concomitant systemic autoimmune disease. Advise fertile anti-Ro positive women about the risk of foetal congenital heart block and the need of frequent ultrasound examination during pregnancy.

8 Treatment

No treatment can modify the evolution of SS, but improvement in quality of life may be achieved. A systematic review highlights the limited evidence available for the drugs most frequently used in primary SS and the difficulties in offering therapeutic recommendations (Ramos-Casals et al, 2010a). The therapeutic management of SS focuses mainly on the control of sicca features, using substitutive and oral muscarinic agents, while glucocorticoids and immunosuppressive agents play a key role in the treatment of extra glandular manifestations.

Basic measures for dry mouth:

Preventive measures against dry mouth include maintenance of good hydration, avoid medication that may worsen oral dryness and avoid low-humidity environments. Patients should be recommended to avoid acidic beverages like cola, coffee, herbal tea and energy drinks. Topical saliva stimulation can benefit from sugar-free candies and chewing gums. Dental care includes regular visit to the dentist, avoid high sugar foods that may favour dental caries, use of dental floss after each meal and use fluoride toothpaste specially developed for dry mouth. We recommend the consumption of water together with meals to facilitate swallowing.

Basic measures for dry eye:

We recommend avoidance of aggravating factors like dry or windy environments, irritants and smoke. Patients can benefit from wraparound sunglasses to conserve tear film. Room humidifiers are useful and warm compresses over the eye may improve meibomian gland secretion.

8.1 Main drugs: synthesis of the evidence

8.1.1 Topical drugs

8.1.1.1 Saliva substitutes

Saliva substitutes are used in clinical practice as the first therapeutic approach in patients with a dry mouth, especially in those with mild symptoms, as they have no significant side effects and have specific benefits for nocturnal dryness.

Topical fluorides are recommended to reduce the incidence, arrest of coronal or root caries. Chlorhexidine and no fluoride remineralizing agents may be considered as an adjunct therapy but the strength of recommendation is weak.

Fungal infection are very common and should be treated with nystatin and ketoconazole.

8.1.1.2 Eye drops

- Several studies have analysed the use of topical eye drops, mainly containing sodium hyaluronate and hydroxypropylmethylcellulose as active principles. All studies found significant improvements from baseline measurements.
- Non-steroidal anti-inflammatory drugs and glucocorticoids. Limited evidence is available for the use of drops containing topical non-steroidal anti-inflammatory drugs (NSAIDs)/glucocorticoids in patients with primary SS. Side effects are the key point to consider when using these eye drops.
- Cyclosporine A. In 2002, an ophthalmic formulation containing cyclosporine A (CsA) was approved by the Food and Drug Administration (FDA) to treat dry eye disease. The dose recommended is 0.05% CsA drops twice daily. Of the adverse events that occurred, most were mild-to-moderate and transient, and only 2% of patients discontinued because of burning and stinging.
- Autologous serum tears are obtained by dilution of patients sera and are useful for more severe disease.

8.1.1.3 Punctual occlusion

Temporary or permanent punctual plugs may be useful for patients with moderate to severe ocular dryness with no response to artificial- tears, lubricants or topical cyclosporine. This should be performed by eye care professionals. The occlusion can be performed in the upper or lower canaliculus. This is a simple and well tolerated procedure but sometimes the patient rejects the plugs.

8.1.2 Systemic drugs

8.1.2.1 Secretagogues

For patients with SS with residual salivary gland function, stimulation of saliva flow with a secretagogue is the preferred treatment. Some choleric (anetholtrithione) and mucolytic (bromhexine, N-acetylcysteine) agents have been used as secretagogues in primary SS since the 1980s, although without solid scientific evidence.

Two muscarinic agonists (pilocarpine and cevimeline) are licensed for the treatment of sicca symptoms in SS. These agents stimulate the M1 and M3 receptors present on salivary glands, leading to increase secretory function. The usual dose for pilocarpine is 5mg four times a day, and for cevimeline 30mg three times a day. Patients should start with one dose daily for a week and if tolerated it should be gradually increased. The response may frequently be delayed, so a three month trial is suggested.

Omega 6 essentials fatty acids are a novel treatment under study.

8.1.2.2 Glucocorticoids

The use of glucocorticoids in clinical practice in patients with primary SS is not supported by reliable scientific evidence, since no study has specifically evaluated their use, but in some cases like arthritis and for extra glandular SS features it is a useful tool. It should be used in the minimal possible dose and for short time. The use of systemic glucocorticoids has been associated with a higher rate of adverse events, including increased appetite and weight gain and a twofold higher incidence of diabetes mellitus.

8.1.2.3 Antimalarial agents

The use of antimalarial agents in primary SS is based on their use in similar diseases, such as RA and SLE. A retrospective study of 50 patients described significant improvements in sicca features, parotid gland enlargement, oral infection, myalgia, arthralgia, fatigue and joint swelling after 12 months of hydroxychloroquine treatment (Fox et al, 1996), while other studies found significant improvements in baseline analytical and immunological parameters. Hydroxychloroquine is preferred over chloroquine, and the usual dose is 6,5mg/kg/day. As it may produce maculopathy it is recommended an ophthalmologic evaluation prior it's use and as follow-up, including colour vision testing and ocular fundus exam.

8.1.2.4 Immunosuppressive agents

The use of immunosuppressive agents in primary SS is based on the same level of evidence as that for glucocorticoids. Several studies with a low number of patients have analysed the use of methotrexate (MTX), leflunomide, azathioprine (AZA) and mycophenolic acid and found limited benefits for sicca features. However, they are useful for specific indications;

- methotrexate and leflunomide for arthritis
- azathioprine for lung and neurological involvement
- mycophenolic acid for renal involvement
- cyclosporine for neurological involvement
- IVIG for neurological involvement and congenital heart block during pregnancy.

The benefit: risk ratio should always be taken into consideration before their prescription. further studies with a larger sample size and using the ESPPRI and ESSDAI as outcome measure are needed.

8.1.3 Biological therapies

The emergence of biological therapies has increased the therapeutic armamentarium available for treating SS, but their use is limited by the lack of licensing. More than 20 studies have analysed the use of seven biological agents in primary SS (table 3): two anti-TNF agents (infliximab—a monoclonal antibody against TNF, and etanercept—a recombinant soluble TNF receptor), three B cell targeted therapies (rituximab—a monoclonal antibody against CD20, epratuzumab—a monoclonal antibody against CD22, and belimumab—a monoclonal antibody against BAFF), a T cell targeted therapy (abatacept) and IFN α .

Randomised controlled trials (RCTs) have demonstrated the lack of efficacy of anti-TNF agents and promising results for B cell-depleting agents (Ramos-Casals et al, 2012). Four recent studies evaluated the use of rituximab in patients with primary SS. Gottenberg et al (2013a*) studied the use of rituximab in 78 patients with SS with systemic involvement and found an overall efficacy of 60%, while Carubbi et al (2013) found a faster and more-pronounced ESSDAI reduction in patients treated with rituximab than in those treated conventionally. In contrast, the successful use of rituximab in the most-prominent triad of symptoms (dryness, fatigue and pain) is not clear. St Clair et al (2013) found only modest improvements in a small open-label trial of 12 patients treated with rituximab, while recent data from a French RCT of 120 patients found no significant changes in the primary outcome (Devauchelle-Pensec et al, 2014). Almost the same results for sicca manifestations were seen even when rituximab was given for 24 months (Carubbi et al, 2013).

Several studies have supported a role for BLYS in the pathogenesis of primary SS (Ramos-Casals, 2013), suggesting that blocking of BLYS might be a potential therapeutic approach. Mariette et al (2013*) were the first to use belimumab (10 mg/kg at weeks 0, 2 and 4 weeks, and then every 4 weeks to week 24) in 30 patients with primary SS. The primary endpoint was defined as an improvement in two or more items (dryness, fatigue, pain, systemic activity and B cell biomarkers) and was achieved in 18 (60%) patients, together with a significant reduction in the ESSDAI score.

Conclusions cannot yet be reached about the recent use of CLA4Ig (abatacept) in primary SS, because of the small number of patients (Adler et al, 2013; Meiners et al, 2014).

Table 3 Studies that have analysed the use of biological agents in primary Sjögren's syndrome (SS) (2004–2014)

Author (year)	Biological agent	Study design	Number of patients with primary SS	Main therapeutic indication
Mariette <i>et al</i> (2004)	Infliximab	RCT	103	Active disease
Zandbelt <i>et al</i> (2004)	Etanercept	Open-label	15	Not defined
Sankar <i>et al</i> (2004)	Etanercept	RCT	14	Not defined
Pijpe <i>et al</i> (2005)	Rituximab	Open-label	15	Early disease + lymphoma
Gottenberg <i>et al</i> (2005)	Rituximab	Retrospective	6	Systemic
Seror <i>et al</i> (2007)	Rituximab	Retrospective	16	Systemic involvement
Devauchelle-Pensec <i>et al</i> (2007)	Rituximab	Open-label	16	Active disease
Meijer <i>et al</i> (2010)	Rituximab	RCT	30	Salivary flow rate
Dass <i>et al</i> (2008)	Rituximab	RCT	17	Fatigue
Vasil'ev <i>et al</i> (2009)	Rituximab	Retrospective	10	Systemic involvement
Ramos-Casals <i>et al</i> (2010c)	Rituximab	Retrospective	15	Systemic
Pollard <i>et al</i> (2011)	Rituximab	Retrospective	19	MALT lymphoma
Zhou <i>et al</i> (2012)	Rituximab	Retrospective	4	Thrombocytopenia
Mekinian <i>et al</i> (2012a)	Rituximab	Retrospective	11	CNS involvement
Voulgarelis <i>et al</i> (2012)	Rituximab	Retrospective	26	MALT lymphoma, NMZL, DLBCL
Mekinian <i>et al</i> (2012b)	Rituximab	Retrospective	17	Peripheral neuropathy
Gottenberg <i>et al</i> (2013a*)	Rituximab	Retrospective	78	Systemic disease
Carubbi <i>et al</i> (2013)	Rituximab	Case-control	41	Early/active disease
St Clair <i>et al</i> (2013)	Rituximab	Open-label	12	Active disease
Mariette <i>et al</i> (2013*)	Belimumab	Open-label	30	Active/systemic disease
Devauchelle-Pensec <i>et al</i> (2014)	Rituximab	RCT	120	Active disease

CNS, central nervous system; DLBCL, diffuse large B cell lymphoma; MALT, mucosa-associated lymphoid tissue; NMZL, nodal marginal-zone B cell lymphoma; RCT, randomised controlled trial.

8.2 Therapeutic scenarios

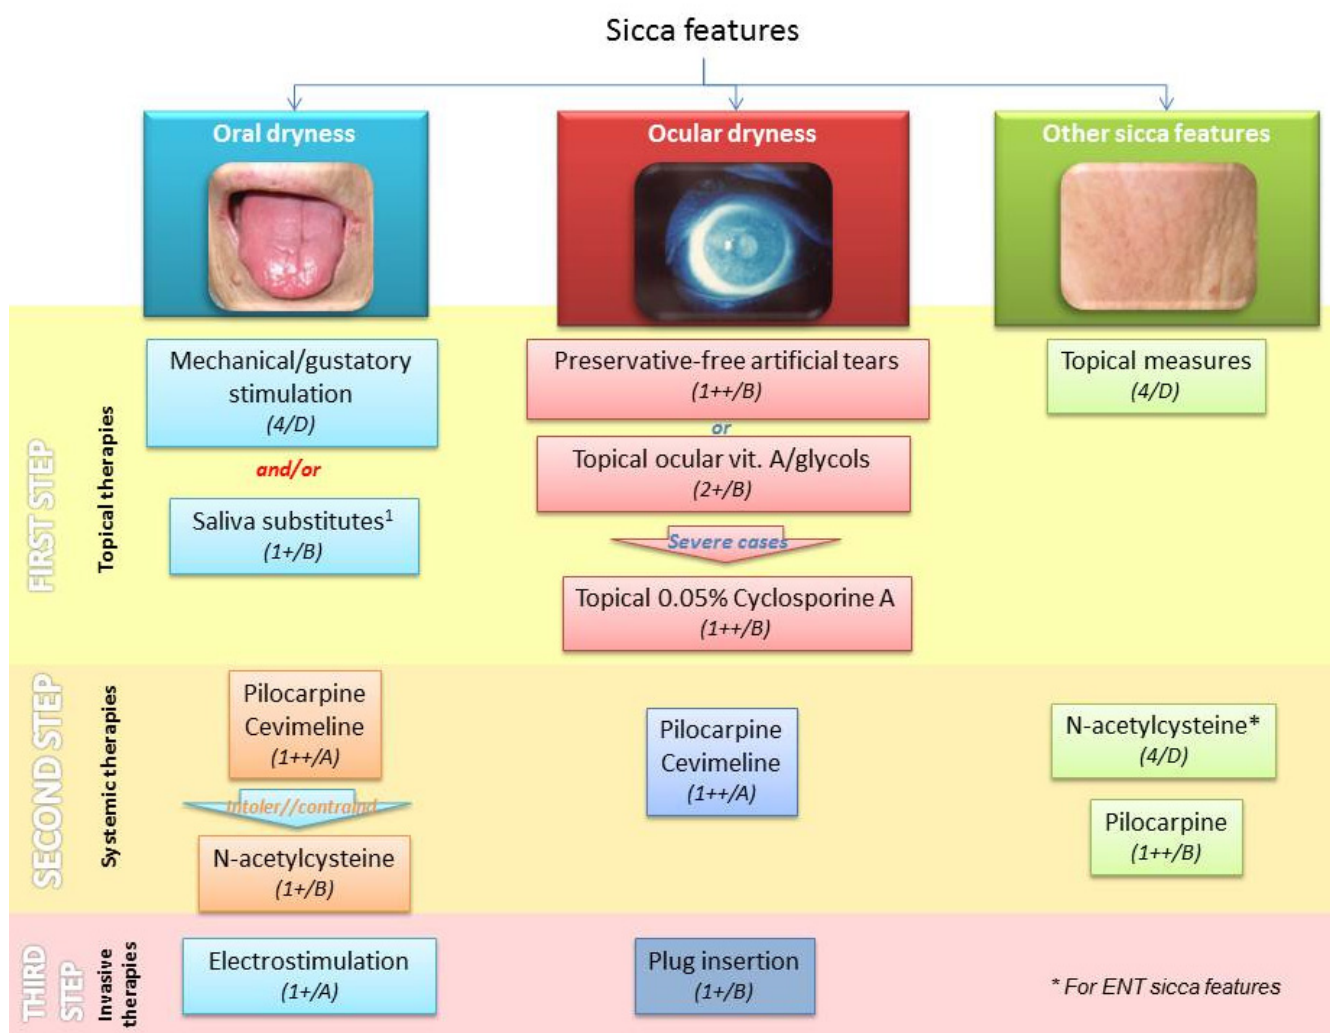

8.2.1 Management of sicca features

The primary therapeutic approach for sicca manifestations should be symptomatic, using artificial tears and saliva substitutes (figure 14)—a recommendation based on reported studies that support their daily use without any kind of side effects and with improvements in the quality of life. However, the available data on treatment for oral dryness does not show conclusively that one specific saliva substitute is better than another in SS (Furness *et al*, 2011). More than one substitute should always be tried, especially when there is poor

tolerance to the first agent. However, patients with acceptable salivary flow outputs may have a poor tolerance due to the sticky feeling caused by saliva substitutes; in these patients, mechanical/gustatory stimulation may be useful. The use of anticholinergic drugs, alcohol (including mouthwashes and fluoride rinses that contain alcohol) and smoking should be discouraged, while non-pharmacological approaches (water intake, mechanical/gustatory stimulation with sugar-free gums and candies, fluoride toothpaste) may be useful.

Other measure useful for xerodermia include the use of neutral soaps, sun protection and body lotions, while topical oestrogens and lubricants may be useful to treat dyspareunia.

Figure 14 Therapeutic management of sicca features.

Patients with severe sicca features affecting their quality of life may require a more intensive therapeutic approach.

- For patients with moderate/severe oral dryness and residual salivary gland function, oral muscarinic agonists (pilocarpine or cevimeline) are the preferred treatment, as long as contraindications are taken into account (figure 14). The best efficacy/side effects ratio dose is 5 mg/6 h for pilocarpine and 30 mg/8 h for cevimeline. No studies have compared the efficacy of the two drugs. Tolerance must be considered, with a frequency of reported adverse events as high as 40%, which include palpitations, sweating, increased urinary frequency, flushing (these 2 more common for pilocarpine) and diarrhoea (more common for cevimeline). In patients with intolerance to muscarinic agonists, N-acetylcysteine may be an alternative.
- Patients with severe or refractory keratoconjunctivitis sicca may require the addition of topical anti-inflammatory agents. Ocular NSAIDs or glucocorticoids should only be prescribed by ophthalmologists for the minimum time necessary, as adverse events seem to be more frequently reported after continued use longer than 2 weeks. In contrast, controlled trials support the use of topical 0.05% CsA twice daily, which has an acceptable safety profile, although no further benefits were seen beyond 6 months of treatment.
- Meibomian gland inflammation can be treated with topical tetracycline.

8.2.2 Management of general symptoms

Patients with primary SS often present with non-specific general symptoms, including non-inflammatory muscle and joint involvement, fatigue and weakness, which may have a much greater impact on the quality of life than sicca features. In these patients, the first step should be a differential diagnosis with associated conditions such as hypothyroidism, neoplasia, depression and, especially, fibromyalgia, which is reported in 22–33% of patients with primary SS and may influence both the patient and physician global health status assessment. The positive effect of aerobic exercise on depression, physical capacity and fatigue was shown in a controlled trial (Strombeck et al, 2007). In patients presenting without severe non-exocrine manifestations this approach should be chosen as the first-line (or at least parallel) therapy for pain, depression and fatigue in view of its low cost, general health-promoting effects and lack of potential side effects compared with drugs. Taking into account the chronic but rarely disabling nature of the disease, coping strategies should be promoted—for example, by contact with a local self-help group/patient association.

After discarding these processes, hydroxychloroquine should be the keystone drug, with clinical benefits being reported beyond fatigue and musculoskeletal pain; uncontrolled studies found additional improvements in subjective and objective sicca features, reductions in parotid enlargement and oral infections and improvements in analytical and immunological parameters.

Biological agents tested in primary SS have been associated with significant improvements in fatigue (including one small RCT using rituximab). Studies with rituximab showed good results for systemic involvement, but should be considered, at most, modest for the triad of dryness, pain and fatigue. It is worth noting that the available data are based in subjective measures using mostly visual analogue scales. We consider that the off-

label use of these new drugs to treat only general symptoms (even when severe) is not warranted. Further studies with objective outcome measures are needed to improve treatment recommendations.

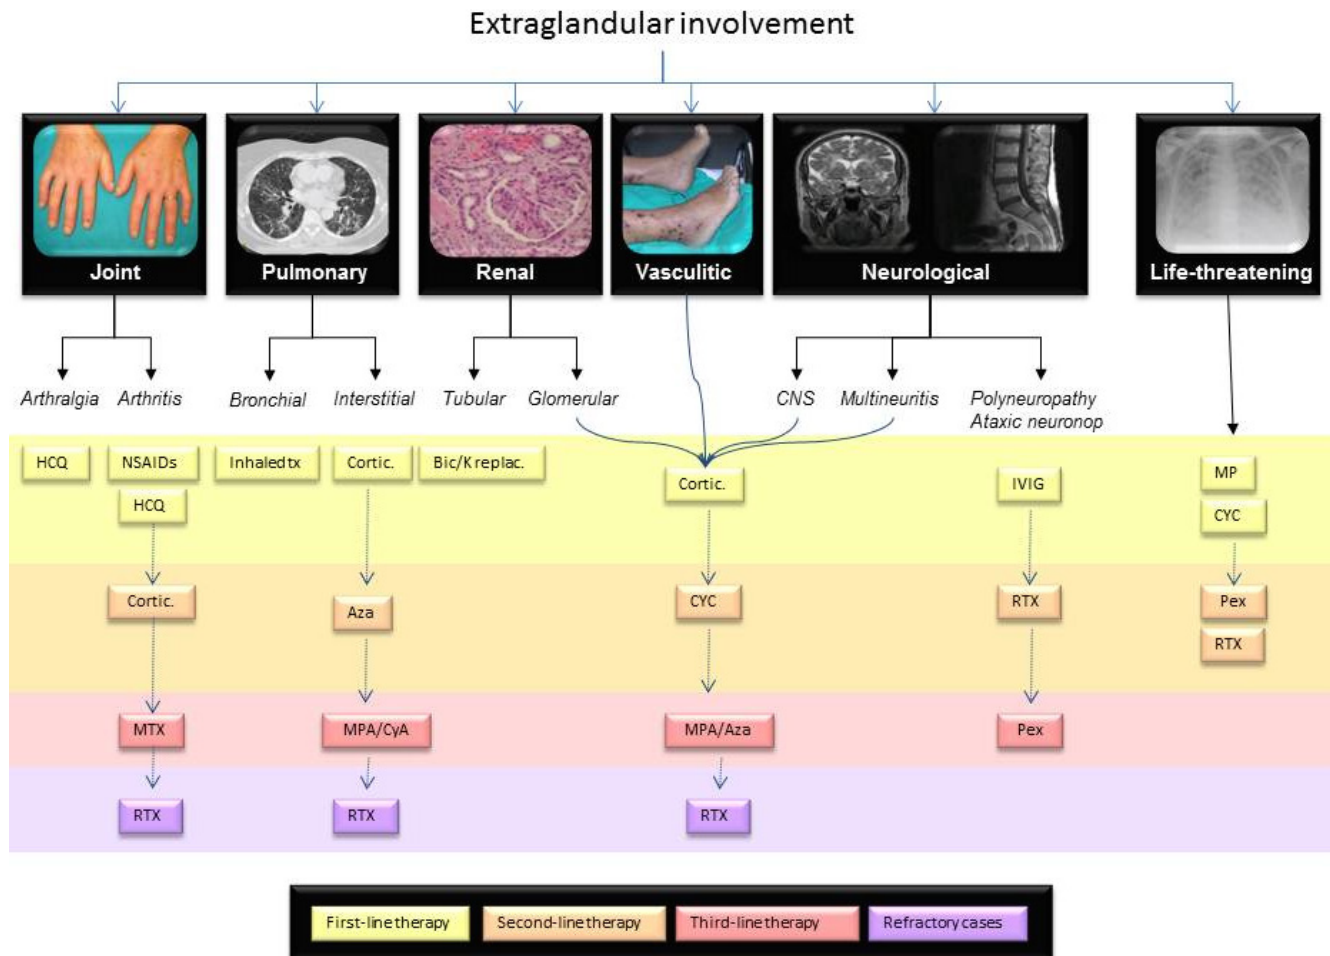

8.2.3 Management of systemic involvement

As a rule, the management of extra glandular features should be organ-specific, with glucocorticoids and immunosuppressive agents limited to potentially severe situations. NSAIDs usually provide relief from the minor musculoskeletal symptoms of SS, and from painful parotid swelling. Hydroxychloroquine may be used in patients with fatigue, arthralgias and myalgias. For patients with moderate extra glandular involvement (mainly arthritis, extensive cutaneous purpura and non-severe peripheral neuropathy), 0.5 mg/kg/day of prednisone may suffice. For patients with internal organ involvement (pulmonary alveolitis, glomerulonephritis or severe neurological features), a combination of prednisone and immunosuppressive agents (cyclophosphamide (CYC), AZA or mycophenolate mofetil) is suggested.

Some retrospective studies and case series have specifically analysed the use of glucocorticoids and immunosuppressive agents in organ-specific involvement (Kassan and Moutsopoulos, 2004; Fox, 2005; Ramos-Casals et al, 2010b*). The most frequently used immunosuppressive agents are AZA in interstitial lung disease, MTX in joint involvement and CYC for glomerulonephritis, vasculitis, multiple neuritis and CNS involvement (figure 15). In contrast, some extra glandular features, such as interstitial nephritis or ataxic neuronopathy, seem to have a poor response to glucocorticoids and immunosuppressive agents.

Evidence suggests that rituximab may be considered in patients with systemic involvement refractory to standard treatment (lack of response or intolerance to glucocorticoids and immunosuppressive agents) (Engel et al, 2011*). The amount and quality of evidence on the off-label use of rituximab in SS-related extra glandular features is greater than that reported for the use of the standard options (glucocorticoids and immunosuppressive agents), although a reasonable assessment of the risk of serious adverse events versus the benefits of treatment should be always made on an individual basis.

Figure 15 Treatment of extra glandular features. AZA, azathioprine; Cortic, glucocorticoids; CYC, cyclophosphamide; HCQ, hydroxychloroquine; IVIG, intravenous immunoglobulins; MP, methylprednisolone; MPA, mycophenolic acid; MTX, methotrexate; NSAIDs, non-steroidal anti-inflammatory drugs; Pex, plasma exchanges; RTX, rituximab; tx, treatment.

8.2.4 Management of life-threatening situations

Severe, life-threatening involvement has rarely been reported in primary SS, and accounts for nearly 10% of deaths (Brito-Zerón et al, 2008). Vasculitis (overwhelmingly cryoglobulinaemic) is the main cause of life-threatening presentation of primary SS, affecting vital organs such as the kidneys, the lungs and the gastrointestinal tract. Other severe involvements included CNS features, progressive ataxic neuropathy, pulmonary arterial hypertension and severe cytopenia (Ramos-Casals et al, 2011). Scarce evidence, taken together with expert review, suggests that methylprednisolone and CYC pulses should be used in patients with severe systemic vasculitis or CNS involvement, with plasma exchange being added in the most severe situations (Pollard et al, 2011; Ramos-Casals et al, 2011). Combined treatment with rituximab plus cyclophosphamide/doxorubicin/vincristine/prednisone (R-CHOP) is highly recommended for SS-associated B cell aggressive non-Hodgkin's lymphomas, under the guidance of an experienced haematologist (Voulgarelis et al, 2004, Voulgarelis et al, 2006).

9 Lymphoma in autoimmune diseases other than primary SS

We discussed the increased risk of lymphoma in primary SS, the autoimmune disease in which the risk of lymphoma is the highest. An increased risk of B cell lymphoma, especially diffuse large B-cell lymphoma and marginal zone lymphoma, is also found in other autoimmune diseases. Chronic immune stimulation, genetic and environmental factors and some immunosuppressive drugs might be involved in lymphomagenesis in these patients (Dias and Isenberg, 2011). In addition, recent studies have also reported an increased risk of Hodgkin's lymphoma (HL) associated with a personal history of several autoimmune diseases, including RA, SLE or sarcoidosis, among others (Fallah et al, 2014).

9.1 Re-evaluation of the risk of non-Hodgkin's and Hodgkin's lymphoma

Studies have re-evaluated the risk of non-Hodgkin's and Hodgkin's lymphoma in autoimmune diseases. The first study compared the prevalence of registered autoimmune disease in 3055 patients with a recent diagnosis of lymphoma compared with 3187 age- and sex-matched controls. The risk of lymphoma was increased in four autoimmune diseases, as mentioned in table 4 (Smedby et al, 2006).

Table 4 Relative risk of NHL in autoimmune diseases

Autoimmune diseases	Relative risk of NHL (*)
RA	1.5 (1.1 to 1.9)
SLE	4.5 (1.0 to 21)
pSS	6.1 (1.4 to 27)
Coeliac disease	2.1 (1.0 to 4.8)

**Relative risks are provided as odds ratios (ORs) with 95% confidence intervals and are adjusted for age (in 5-year intervals) and sex.*

NHL, non-Hodgkin's lymphoma; pSS, primary Sjögren's syndrome; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

This study is interesting but it is a case–control study, which depends on the unbiased selection of controls. The incidence of lymphoma in patients with autoimmune diseases might be slightly underestimated since the prevalence of some autoimmune diseases in the control population seems high—notably, the prevalence of RA, which affects 2.8% of the control population versus 1.5% of the general population after adjustment for age and sex. This prevalence might be overestimated (for example, prevalence of RA in France is 0.3%).

The second study examined the prevalence of records of autoimmune disease in 7476 patients with a recent diagnosis of HL compared with 18 573 age- and sex-matched controls. The results showed that HL, which is 10 times more infrequent than non-Hodgkin's lymphoma (NHL), was also increased in autoimmune diseases (table 5).

Table 5 Relative risk of HL in autoimmune diseases

Autoimmune diseases	Relative risk of HL*
RA	2.7 (1.9 to 4.0)
SLE	5.8 (2.2 to 15.1)
pSS	10.3 (0.9 to 120)
Sarcoidosis	14.1 (5.4 to 36)

*Relative risks are provided as odds ratios (ORs) with 95% confidence intervals and are adjusted for age (in 5-year intervals) and sex.

HL, Hodgkin's lymphoma; pSS, primary Sjögren's syndrome; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

The third study, a meta-analysis, included six studies of lupus (8700 patients), nine studies of RA (95 104 patients) and five studies of primary SS (1300 patients). Table 6 summarises the main results of the meta-analysis (Zintzaras et al, 2005).

Table 6 Risk of lymphoma in autoimmune diseases

Autoimmune diseases	Risk of lymphoma*
RA	3.9 (2.5 to 5.9)
SLE	7.4 (3.3 to 17)
pSS	18.8 (9.5 to 37.3)

*Standardised incidence rate estimates of development of NHL with the corresponding 95% confidence intervals.

NHL, non-Hodgkin's lymphoma; pSS, primary Sjögren's syndrome; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

The fourth study analysed the risk of HL in 878 161 Swedish patients diagnosed with 33 different autoimmune diseases between 1964 and 2010; during a mean follow-up of 10 years, 371 incident cases of HL were diagnosed. The overall standardised incidence ratio (SIR) for HL after the diagnosis of autoimmune disease was significantly increased to 2.0 (95% CI 1.8 to 2.2). Specific SIRs for the main autoimmune diseases are summarised in table 7 (Fallah et al, 2014).

Table 7 Risk of Hodgkin's lymphoma (HL) in autoimmune diseases

Autoimmune diseases	Risk of HL*
Autoimmune haemolytic anaemia	19.9 (7.2 to 43.6)
Sarcoidosis	10.3 (7.8 to 13.4)
Systemic lupus erythematosus	8.4 (5.2 to 12.9)
Immune thrombocytopenic purpura	7.0 (3.2 to 13.3)
Polyarteritis nodosa	6.6 (1.2 to 19.5)
Polymyositis/dermatomyositis	6.3 (2.0 to 14.9)
Behçet's disease	5.6 (2.7 to 10.3)
Sjögren's syndrome	5.0 (2.1 to 9.8)
Rheumatoid arthritis	3.2 (2.6 to 3.9)
Polymyalgia rheumatica	2.2 (1.4 to 3.5)
Psoriasis	1.9 (1.3 to 2.6)

*Relative risks are provided as odds ratios (ORs) with 95% confidence intervals.

9.2 Confirmation of the increased risk of lymphoma in patients with SLE

Recent studies have evaluated 16 409 patients with SLE from the Systemic Lupus International Collaborating Clinics (SLICC) cohort (Bernatski et al, 2012) across 30 centres; these patients were followed up for 121 283 (average 7.4) person-years. In total, 644 cancers occurred. Some cancers—notably, haematological malignancies, were substantially increased (SIR = 3.02, 95% CI 2.48 to 3.63), particularly NHL (SIR = 4.39, 95% CI 3.46 to 5.49) and leukaemia.

A specific study evaluated the main characteristics of 75 patients with SLE with lymphoma (72 NHL, three HL) and 4961 cancer-free controls. Most lymphomas were of B cell origin. As is seen in the general population, the lymphoma risk in SLE was higher in male than female patients and increased with age. Lymphomas occurred a mean of 12.4 years (median 10.9) after SLE diagnosis. There was a trend for a greater exposure to CYC and to higher cumulative steroids in patients with lymphoma than in the cancer-free controls. Disease activity itself was not clearly associated with lymphoma risk (Bernatsky et al, 2014).
